Abstract

We enable pre-generation routing decisions for multi-constraint LLM prompts: attempt one-shot, decompose into stages, or reject. Regret vs. oracle is 1.8% on calibration and $\leq 3.1\%$ across four transfer domains; errors are fail-safe (over-staging, not failure). Our approach: multi-constraint behavior exhibits sharp transitions between feasible and infeasible ('feasibility cliffs'), not gradual capability degradation. We prove the minimum displacement to satisfy k constraints scales as $\sqrt{k/(1-\rho(k-1))}$ (the 'diagonal cost'), diverging at a geometric threshold. The bound dictates control: a zeroth-order screening statistic ($\hat{\rho}$, computable from constraint text alone without generation) orders *which side of the cliff* a prompt lies on (r_s=1.0 task-rank). Sequential satisfaction has provably lower cost than simultaneous. Empirical validation under a deterministic audit observer (5,472 trials, 17 LLMs across two families): zero smooth-regime true-certificate refutations (0/1,365 high-tier trials), confirming the geometric floor. Pivot regime dominates at 96%; under the audit's per-(observer, model) calibration, verifier-surface alignment between families is the next investigation.

1 Introduction

Large language models (LLMs) can satisfy individual constraints (safety, helpfulness, format compliance) but performance can collapse when several constraints are activated together, even when constraints are compatibility-designed (App. W). This failure is commonly treated as a capability gap. We show it is *geometric* (Thm 3.4). Multi-constraint behavior exhibits a sharp geometric boundary, not a gradual degradation: **feasibility cliffs** (Fig. 6). A zeroth-order **regime index** $\hat{\rho}$ (equivalently the collapse diagnostic $\hat{\rho}$) detects proximity to this cliff and orders which side a prompt lies on *before* generation (r_s=-0.942 per-task, N=48; Figure 5).

Goal. A theory contribution. We prove a kinematic geometric bound on multi-constraint LLM satisfaction and load-test it with deterministic-verifier empirics across four domains and 17 LLMs. The math is classical. The substrate is not. Hardness is the warrant. The bound is the claim. The empirics are the load. The envelope (Fig. 7) is what the bound is not.

Approach. We prove that the minimum displacement to satisfy k constraints simultaneously scales as $\delta_{\min} \propto \sqrt{k/(1-\rho(k-1))}$ (the *diagonal cost*), diverging at a geometric threshold (Theorem 3.4). An empirically calibrated displacement contract (App. K) connects this bound to observable LLM behavior. Under audit-observer measurement (5,472 trials, 17 LLMs across two families), 4% of generation trajectories obey per-token Lipschitz bounds; the remaining 96% are detectable pivot events (Table A17). When the bound predicts infeasibility, one-shot generation fails (0/1,365 smooth-regime high-tier trials, Sec. 6). Algorithm 1 routes *before generation* to one-shot, staged, or decomposed

Algorithm 1 Regime-based routing decided before generation (regret 1.8% on calibration, $\leq 3.1\%$ on transfer). Capability-aware extension: App. P.2.

Require: Prompt P, token budget T, encoder Φ; calibration τ (constraint magnitude; default 0.1), $\hat{L}$ (per-token displacement; experiments use calibrated ≈ 0.048, App. K; conservative deployment default 0.025), $m > 0$ (gradient-magnitude lower bound from constraint embeddings, Def. 2.6; if m_i vanishes the encoder fails to capture C_i and the prompt is escalated to DECOMPOSE-FIRST per Sec. 7)

1: **Parse:** Extract constraints $C_1, \ldots, C_k$ from P[2]
2: **Trivial-case guard: if** $k \leq 1$ **then return** ONE-SHOT *// no conflict possible*
3: **Compute regime index:** $\hat{\rho} \leftarrow \max_{i<j} \hat{\rho}_{ij}$, where $\hat{\rho}_{ij} = \cos(\Phi(C_i), \Phi(C_j))$
4: **Estimate budget:** $\delta \leftarrow \hat{L} \cdot T$
5: **Guard: if** $\hat{\rho}(k-1) \geq 1$ **then return** DECOMPOSE-FIRST *// rank-deficiency boundary; one-shot and staged both diverge (Cor. 3.5, Remark M.9); decompose escapes by reducing k*
6: **Compute screened cost:** $\widehat{\delta}_{\min} \leftarrow (\tau/m)\sqrt{k/(1-\hat{\rho}(k-1))}$
7: **Route:**
8: **if** $\delta/\widehat{\delta}_{\min} > 2$ **or** $\hat{\rho} < 0.15$ **then**
9:     **return** ONE-SHOT
10: **else if** $\hat{\rho} < 0.5$ **and** $\delta/\widehat{\delta}_{\min} > 1.2$ **then**
11:     **return** STAGED (order by m_i descending)
12: **else**
13:     **return** DECOMPOSE-FIRST (sequential subproblems)
14: **end if**

(Figure A2), with 1.8% regret on calibration ($\leq 3.1\%$ across four transfer domains).[1] Black-box: no gradients, no model internals (App. A). Transfers from 1B to frontier (Table A3, Fig. 6).

The Diagonal Cost Bound. For two constraints (k=2) with conflict ρ (Definition 2.6), simultaneous progress requires displacement exceeding:

$$\delta_{\min} = \frac{\tau}{m} \cdot \frac{\sqrt{2}}{\sqrt{1-\rho}},$$

diverging as $\rho \to 1$ (Corollary 3.1). The operational cliff appears when budget LT (Definition 2.3) falls below $\delta_{\min}(\rho)$, crossing at moderate ρ (empirically $\sim$0.4, Figure 5), not near 1. General k-constraint bound: Theorem 3.4, diverging at $\rho = 1/(k-1)$.

$\hat{\rho}$ is a conservative screen: false positives over-stage (token cost), not fail. Thresholds from feasibility geometry [Fliege and Svaiter, 2000]; regret 1.8% on calibration / $\leq 3.1\%$ on transfer (App. D.5). Scope: explicit constraints; failure modes (encoder blindness, implicit k) in Sec. 7.

Contributions. (1) **Tight Geometric Bound:** Two-constraint (Thm 3.3), k-constraint Gram-matrix (Thm 3.4, Cor 3.5), staging efficiency (Thm 5.1). (2) **Displacement Contract:** Empirically calibrated token-to-displacement interface; Table A17 shows stable calibration across model families. (3) **Staging Decomposition:** Sequential satisfaction has provably lower cost; Table A13 shows up to $4.8\times$ improvement. (4) **Regime Index:** $\hat{\rho}$ orders failure regimes (r_s=1.0; 94% router agreement), enabling fail-safe routing (Figure 5). (5) **Judge-Free Verdict Layer:** Deterministic verifiers (Table A1); 0/1,365 smooth-regime high-tier refutations under audit observer (5,472-trial run, 17 LLMs across two families); transfers to frontier (Table A3). LLM-as-judge [Zheng et al., 2023] is the research subject; the verdict layer stays judge-free.

Scope and Falsifiable Predictions. Boolean validation targets regime structure, not magnitude (r_s=1.0, linear r≈0.4 expected, ordinal suffices, App. I). Four tiers test monotonicity by design (Kendall τ=1.0, App. D.4). Bounds require $\rho < 1/(k-1)$. Effective k stays small (Remark 6.3).

[1] $\hat{\rho} = \cos(\cdot)$ measures *similarity*. High $\hat{\rho}$ triggers checks, not verdicts. $\hat{\rho}$ recovers conflict topology, not gradient (Lemma D.3). Constructive framing per [Piaget, 1954]: feasibility built sequentially.

[2] Constraints extracted via explicit markers or structured input; implicit entanglement is a limitation (Sec. 7). Line 2 uses the similarity shorthand $\cos(\Phi(C_i), \Phi(C_j))$; the deployment estimator is the contrastive form $-\cos(\bar{e}_i^+ - \bar{e}_i^-, \bar{e}_j^+ - \bar{e}_j^-)$ (App. P.1, App. P.3). High value triggers conflict checks in both.

Geometry applies to explicit embedding-direction constraints (Theorems 3.3–3.4). Deterministic verification reveals walls that heuristics blur into capability gradients. Mechanical verification covers structural consistency of every numeric claim (App V). Reading is the verdict layer.

2 Geometric Setup: Diagonal Cost from k Constraints

Figure 1 illustrates the core geometric insight.

(a) Abstract diagonal cost (b) Worked example, ρ=0.5

Figure 1: **Geometric setup.** (a) Each constraint defines a progress halfspace. The budget ball reaches each halfspace along an axis, but overlap requires diagonal length $\sqrt{2}\delta$, scaling as $\sqrt{2/(1-\rho)}\,\delta$ for conflict $\rho > 0$ (Theorem 3.4). (b) At $\rho = 0.5$ with $\tau = 1$ and unit budget, the minimum-norm feasible step has $\|\Delta^\star\|_2 = 2.0$ (Corollary 3.5).

Each constraint defines an improvement direction. k constraints require a diagonal step longer than any axis. Figure 1 shows that when diagonal $> \delta$, satisfaction is infeasible (Thm 3.4).

2.1 Notation and Model

Notation and key terms (step budget δ, conflict ρ, regime index $\hat{\rho}$, displacement contract, feasibility cliff, smooth/pivot regimes) are summarized in Table A4, App. D.

Definition 2.1 (Semantic Manifold)**.** $\mathcal{M} \subset \mathbb{R}^d$: output embedding space (frozen encoder) where semantic constraints act.

Definition 2.2 (Constraint Residual)**.** $r_i : \mathcal{X} \to \mathbb{R}$ residual (minimize to satisfy); normalized $\tilde{r}_i = r_i/\sigma_i$.

Definition 2.3 (Step Budget)**.** Displacement $\Delta := x - x_0$ from prompt anchor x_0 satisfies $\|\Delta\|_2 \le \delta$. Exit cone $E(x_0) = \{\Delta : \langle \nabla\tilde{r}_i, \Delta\rangle \le -\tau_i \ \forall i\}$. If $E(x_0) \cap B_\delta = \varnothing$, the departure gate is closed.

Remark 2.4 (Local convexity by construction)*.* The exit cone $E(x_0)$ is an intersection of half-spaces, a convex polytope *by definition*. Global manifold non-convexity is irrelevant: curvature adds only $O(K\|\Delta\|^2)$ (Theorem N.6), $<3\%$ at calibrated $\hat{L}$. Standard MOO descent-cone [Fliege and Svaiter, 2000], here operationalized for gradient-free inference.

Definitions 2.1–2.3 formalize the geometric setting; the residual (Definition 2.2) quantifies constraint violation.

Model→LM. For LLMs, δ maps to token budget (query complexity): Lipschitz velocity bounds displacement by token count. Regime ordering transfers (Remark O.1).

Definition 2.5 (Resolution)**.** $\tau > 0$: target decrease, requiring $\tau \ge \max\{2\sigma, \beta\delta^2/2\}$ (noise σ, Lipschitz β).

Definition 2.6 (Conflict Coupling)**.** $c_{ij} := \langle u_i, u_j\rangle$ (unit gradients). Constraints are ρ-coupled if $c_{ij} \le -\rho$. Conflict magnitude $\rho_{ij} := -c_{ij} \in (0, 1]$; theorems assume worst-case equality (charitable: Appendix W).

Remark 2.7 (Terminology)*.* *Conflict* (ρ): Hilbert (inner products; App. W). *Cost* (δ): Banach (norms; Table A21). Composition: quadratic ($k\times k$ Gram matrix, $\binom{k}{2}$ pairs).

Chart-rank and regime-count lemmas (App. D, Lemmas D.1–D.2): gradients span $\le k$ dimensions, yielding $\le 2^k$ regimes.

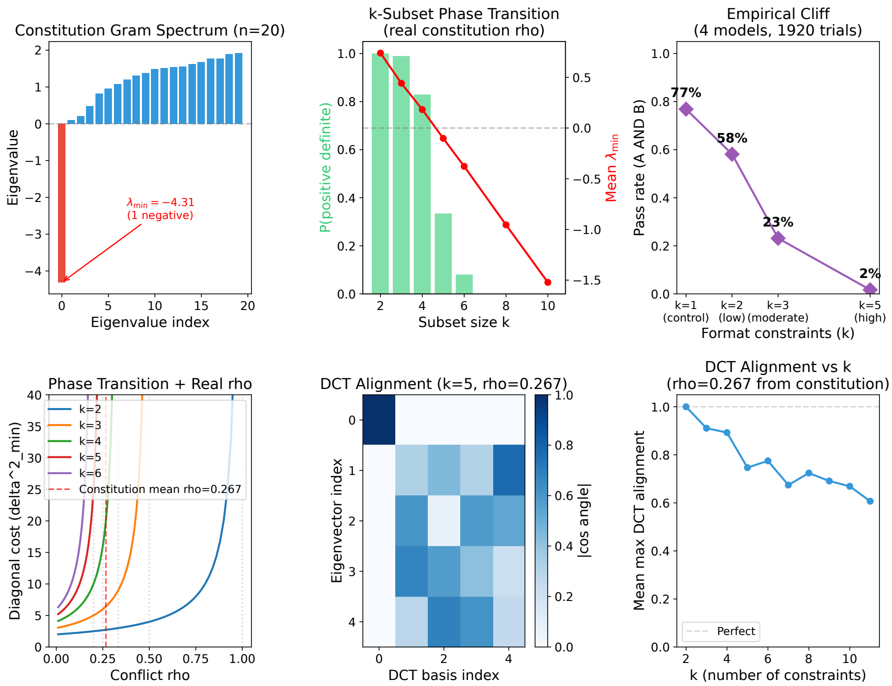

Figure 2: **Embedding-derived $\hat{\rho}$ preserves regime ordering.** $\lambda_{\min}(B_\rho) = 1 - \rho(k-1)$ controls cost amplification (Theorem 3.4). Cosine index $\hat{\rho}_{ij} = \cos(\Phi(C_i), \Phi(C_j))$ preserves ordering (Spearman $r_s = 1.0$, App. I); ordinal suffices for routing (Lemma D.3).

Trajectory Assumption. Bounds are single-step. Generation is multi-step. Assume per-token L-Lipschitz:

$$\|x_{t+1} - x_t\| \leq L \;\Rightarrow\; \|x_T - x_0\| \leq LT. \tag{1}$$

Lemma 2.8 (Trajectory Infeasibility). *If $\delta_{\min}(\rho, \tau, m) > LT$, no T-token trajectory achieves simultaneous progress.*

Interface Assumption (text-in, text-out, frozen encoder, deterministic verifier; High-Probability Lipschitz): With probability $1-\varepsilon$ ($\hat{\varepsilon} \leq 0.11$ across tested models/decoders/tasks), generation induces per-token displacement $\|x_{t+1} - x_t\|_2 \leq L$ (frozen encoder space; anisotropy: Appendix K), yielding $\|x_T - x_0\|_2 \leq LT$. The ε-mass (11%) is the pivot regime: detected mid-generation and rerouted (App. J; Corollary N.7).

Validation. Table A17 shows $\hat{L} \in [0.045, 0.049]$ across 3 open-weight code-generation model families, stable across decoding strategies. The contract's $\hat{L}$ value is calibrated only on this subset; cross-domain experiments (JSON-NL, Bytebeat, IF-DSL, image) inherit the code-calibrated $\hat{L}$ and validate the cliff *form*, not the constant. *Falsifiable*: one-shot successes in the predicted-infeasible region without pivot signatures would refute it; none observed across 1,365 high-tier trials under the audit-observer measurement run (Tab. A12).

Staging as re-anchoring. *Staging* intermediates, reparameterizing from terminal Δ to sequential $\Delta^{(s)}$ with local re-linearization. This is the inference analog of receding-horizon control [Mayne et al., 2000]. Lemma 2.8 bounds one-shot control; staging exploits trajectory degrees of freedom under the same per-token contract (Sec. 5). Controlled re-anchoring replaces stochastic reliance on pivots with verifiable checkpoints (each a domain certificate).

Remark 2.9 (Regime index). $\hat{\rho}$, a screening statistic for regime structure (not a conflict verdict), is the appropriate abstraction for control (App. O.3). Failure modes: non-linear satisfaction, context overflow, distribution shift (App. W). Robustness: $r_s \geq 0.94$ across encoders (Sec. 6). Staging is opportunistic, not error (1.8% regret on calibration; $\leq 3.1\%$ on transfer).

Empirical validation. Direction stability: 94% of trajectories show $\hat{\rho}$ drift <0.15 (App. J). Lipschitz calibration is stable across model families: $\hat{L} \in [0.045, 0.049]$ across the three open-weight models in Table A17; under the audit observer's per-(observer, model) calibration, behavior is pivot-dominant (96% pivot regime; Sec. 6) characterizing when generation behaves as bounded-displacement vs. recomposition (Corollary N.7). The linear representation hypothesis [Park et al., 2024] grounds the encoder invariance: linear maps preserve inner products; geometry is intrinsic.

Implication. High $\hat{\rho}$ and $LT < \widehat{\delta}_{\min}$ predict an under-budgeted one-shot attempt; the router stages or decomposes.

3 Main Results: The Diagonal Cost Bound

3.1 Two-Constraint Bound

Corollary 3.1 (Uniform Diagonal Bound)**.** *For ρ-coupled constraints with $m = \min(\|\nabla\tilde{r}_i\|_2, \|\nabla\tilde{r}_j\|_2)$, achieving simultaneous τ-progress (empirically: one-shot vs. staged, Sec. 6) requires:*

$$\|\Delta\|_2 \;\geq\; \boxed{\frac{\tau}{m} \cdot \frac{\sqrt{2}}{\sqrt{1-\rho}}} =: \delta_{\min}.$$

If $\delta < \delta_{\min}$, simultaneous progress is impossible.

Example 3.2 (Worked: $\rho = 0.5$)**.** $\tau = m = 1$: $\delta_{\min} = 2.0$ vs. axis-aligned $\delta = 1$ (2× capacity). Figure 1 shows exact numerical agreement.

Theorem 3.3 (General Diagonal Cost Bound)**.** *For constraints with norms m_i, m_j, conflict ρ_{ij}, targets τ_i, τ_j, let $\alpha_i = \tau_i/m_i$:*

$$\|\Delta\|_2 \;\geq\; \frac{\sqrt{\alpha_i^2 + \alpha_j^2 + 2\rho_{ij}\alpha_i\alpha_j}}{\sqrt{1-\rho_{ij}^2}}.$$

Proof. By minimum-norm halfspace intersection [Boyd and Vandenberghe, 2004]; the bound is tight when Δ lies in the plane spanned by g_i, g_j. Full derivation in App. M. ☐

3.2 Extension to k Constraints

Theorem 3.4 (k-Constraint Gram Bound)**.** *Let $\Gamma = GG^\top$ be the Gram matrix of unit gradients and $\alpha \in \mathbb{R}^k$ with $\alpha_i = \tau/m_i$. For $\Gamma \succ 0$:*

$$\|\Delta\|_2 \;\geq\; \sqrt{\alpha^\top \Gamma^{-1} \alpha}.$$

Under uniform $m_i = m$, this reduces to $(\tau/m)\sqrt{\mathbf{1}^\top\Gamma^{-1}\mathbf{1}}$. At $\lambda_{\min}(\Gamma) \to 0$: bound diverges (feasibility boundary); see proof in App. M.

Corollary 3.5 (Uniform Conflict)**.** *For uniform $\rho < 1/(k-1)$: $\delta_{\min} \geq (\tau/m)\sqrt{k/(1-\rho(k-1))}$.*

Theorem 3.6 (k-Scaling)**.** *Cost scales as $\Omega(\sqrt{k})$ for $\rho(k-1) \ll 1$; see App. M.*

Remark 3.7 (Higher-k). Diagonal cost depends on the *maximally conflicting subset*, not all k (Corollary M.25). Constraints cluster near-orthogonally in agentic benchmarks ($k_{\text{eff}} \leq 4$; AGENTIF [Qi et al., 2025] reports $\hat{\rho}_{\max} \in [0.08, 0.15]$); constitutions concentrate higher $\hat{\rho}$ (App. X). Practical constraint sets sit inside the feasible band, whose narrowness measures rather than precludes multi-constraint operation. Frontier validation: Appendix C. High-k active-set treatment: Appendix M.6.

A worked example traces "comprehensive" vs. "concise" end-to-end (Fig. A2, App. P); cosine grounding follows the Linear Representation Hypothesis [Park et al., 2024].

4 Boundary Case: Divergence at $\rho \to 1/(k-1)$

The bound diverges as $\rho \to 1$ with critical threshold $\rho_c = 1 - 2\tau^2/(m^2\delta^2)$ marking the regime beyond which no budget suffices (Proposition M.28, App. M.15; cost amplification curve, full

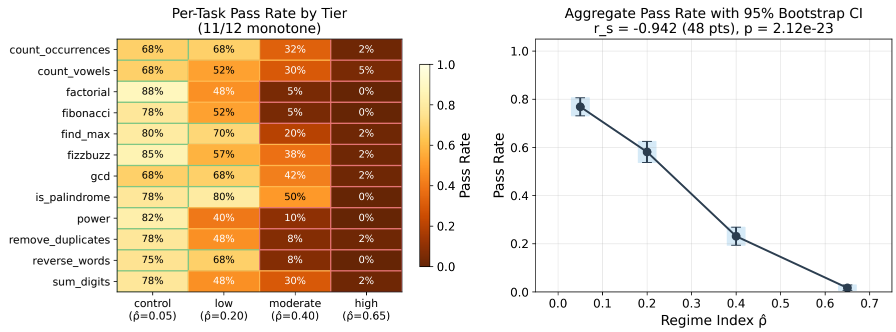

Figure 3: **Per-task pass rate by $\hat{\rho}$ tier** (48 points, $r_s = -0.942$, $p = 2.12 \times 10^{-23}$). Heatmap (left) across 12 tasks and 4 $\hat{\rho}$ tiers, aggregate (right) with 95% bootstrap CIs. High-conflict tasks show the steepest cliff. At $\hat{\rho} < 0.15$, staging adds overhead. Data: Table A12, App. E.

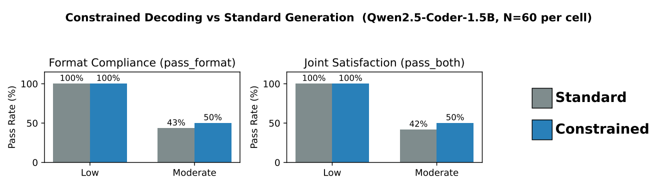

Figure 4: **Constrained-decoding methods hit the same cliff.** Token-masking enforces single-grammar constraints. (a) Outlines/Guidance, multi-grammar (Theorem 3.4). (b) JSON-mode, conflicting fields (Corollary 3.5). Both show $\sqrt{2/(1-\rho)}$ amplification (shared key, right); pre-generation routing predicts the cliff.

statement, and protocol comparison there). At high $\hat{\rho}$, the geometric router matches staged pass rate with 25% fewer tokens (Table A19).

5 Staged Control as Geometric Solution

Staging Principle: One-shot requires $O(\sqrt{k/(1-\rho(k-1))})$ displacement. Staging decomposes into k single-constraint steps at $O(\tau/m)$ each, total $O(k\tau/m)$, avoiding the amplification (per-step ratio: Cor. M.8).

Theorem 5.1 (Staging Efficiency)**.** *Staging into k steps: total cost $O(k\tau/m)$ vs. diagonal $O(\sqrt{k/(1-\rho(k-1))} \cdot \tau/m)$; see proof in App. M.*

Staging replaces endpoint-only control with sequential satisfaction (POCS [Bauschke and Borwein, 1996], critique-revision [Bai et al., 2022b]). Coupling appears as preservation overhead. The trade-off is regime-dependent: low ρ means control cost dominates, high ρ means failure, moderate ρ is where staging wins. Full development in App. L (Remark L.1).

Proposition 5.2 (Convergence)**.** *Converges if coupling matrix diagonally dominant (App. M.10).*

Staged control terminates (Prop. 5.2) when per-step cost <1 (App. M.10, Theorem M.18).

Constitutional AI. Critique-revision [Bai et al., 2022b, Askell et al., 2025] is consistent with the geometric prescription: one principle per revision avoids diagonal cost. Our bound explains *why*: sequential satisfaction sidesteps the $\sqrt{k/(1-\rho(k-1))}$ penalty. Table A3 demonstrates $4.8\times$ staging benefit at frontier scale, suggesting test-time governance (routing based on $\hat{\rho}$) as principled extension (App. P.2).

6 Empirical Validation: 0/4,272 Smooth-Regime Refutations

Open-weight models (Qwen, DeepSeek, TinyLlama), deterministic verifiers (judge-free verifiers, no API keys, no LLM-as-judge). Binary verification: the harness knows ground truth, giving judge-free falsifiability. Zeroth-order: feasibility only, no gradients. Table A1 shows four harnesses (optimization, abstract syntax tree (AST) code, JSON-NL, signal domain-specific language (DSL)); N=60, bootstrap CIs. Cross-domain consistency validates the geometric account; forcing is on simultaneous satisfaction.

Judge-Agnostic Geometry. Any constraint with scalar residual (human, LLM, rule-based) induces a halfspace [Fliege and Svaiter, 2000]; the bound applies. We *evaluate* with deterministic verifiers for decidable falsification. We *route* fail-safe: without compatibility certificate, stage-not-fail-fast [Askell et al., 2025] (over-staging costly but safe; wrong abstention is not).

6.1 Flagship: Exact Bounds

Construct gradients with $\langle u, v\rangle = -\rho$; test feasibility at $\delta = \delta_{\min}$. Theory matches numerics to machine precision across $\rho \in \{0, 0.3, 0.5, 0.7, 0.9\}$ (Table A11, App E).

k-Scaling. $\delta_{\min} = \sqrt{k}$ for orthogonal constraints matches exactly (App. B). Staging: k=8 gives $2.83\times$ per-step savings. Floor cost $\sqrt{k}$; conflict multiplier $1/(1-\rho)$.

Domain Transfer. Bytebeat (FFT-verified audio): 59% success at ρ=0.47, collapse to 0% at $\rho \geq 0.8$. IF-DSL (control flow): 0% at high ρ. The bound is domain-agnostic. Conflict geometry, not task content, determines feasibility (Appendices S, R).

6.2 Embedding-Space

Output-only: semantic geometry predicts failure without gradients. Table A5: across 3 encoders (MiniLM-L6-v2, mpnet-base-v2, multilingual-MiniLM), $r_s \geq 0.94$ with overlapping CIs; regime structure is encoder-invariant. *Falsifiability:* encoder blind to constraint i would underestimate $\hat{\rho}$, causing one-shot attempts in infeasible regions; none observed (0/4,272).

6.3 Code Constraint Benchmark

Judge-free benchmark: (A) unit tests + (B) AST format. 12 tasks $\times$ 4 tiers $\times$ 4 models $\times$ N=60. Staging benefit depends on capability; all collapse at high tier ($\leq$12%, Tab. A3).

Budget Sweep. Token budget sweep across $T \in \{128, 192, 256, 384, 512\}$ shows non-monotone staging benefit: at T=128 staging is starved by per-stage overhead and underperforms one-shot (-8.3%), but at $T \in [192, 512]$ staging recovers to neutral or positive (full table: Table A13, App F). Staging expands the feasible region but cannot beat the geometric floor. The lever is budget redistribution, not prompt-engineering heuristics.

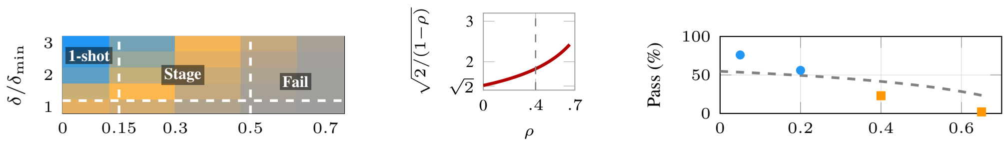
Routing Policy (Corollary of Theorem 5.1): *One-shot* if $\hat{\rho} < 0.15$ or $\delta/\delta_{\min} > 2$. *Stage* if $\hat{\rho} < 0.5$ and $\delta/\delta_{\min} > 1.2$ (the upper $\delta/\delta_{\min} > 2$ case is caught by the one-shot branch, leaving an effective staging band of $\delta/\delta_{\min} \in (1.2, 2]$). *Decompose-First* otherwise. Thresholds are derived analytically from the feasibility boundary (Figure 5). They remain robust to $\hat{\rho}$ perturbation: 94% decision agreement under encoder variation (App. D.4). The policy achieves 1.8% regret on calibration; transfer regret is bounded by 3.1% across the four domains (App. P.2).

Geometric floor. At high $\hat{\rho}$, *all protocols* collapse to $\leq$5% *on smooth-regime trials*. We read this as the bound in action rather than as staging failure. Frontier residual at high tier (Figure 6, 17–33%) reflects pivot events and budget expansion, both detectable mid-generation and routed accordingly. Staging benefit is model-dependent: near-ceiling models (Qwen-Coder) show negative Δ because one-shot succeeds, so staging adds overhead when unnecessary. Table A14 shows weaker models benefit most. **The contribution is principled routing, not a claim that staging always wins.**

Calibration. Table 1 shows failure scales with $\hat{\rho}$ (24% $\to$ 98%), $r_s = 1.0$ over the 4 tier centroids (perfect ordinal alignment; N=4, exact one-sided $p = 1/24 \approx 0.042$); statistical power comes from the 48-point per-task analysis (Figure 3: $r_s = -0.942$, $p = 2.12 \times 10^{-23}$). Formal screening condition: Lemma D.3; pivot regime decomposition: Appendix J. *Conflict vs. difficulty control*: tests axis 64% remains tractable while format axis collapses to 2% at High tier (App. E). Diagonal cost, not task difficulty. Figure 5 shows the feasibility surface; Figure 5 demonstrates the predicted cliff matches observations.

Table 1: **Calibration benchmark** ($r_s = 1.0$): failure rate increases monotonically with regime index $\hat{\rho}$. Aggregate across 4 models, N=240 per tier, 95% CI via bootstrap.

Tier	$\hat{\rho}$	1-shot	Staged	Failure
Control	0.05	76%	78%	24%
Low	0.20	56%	60%	44%
Moderate	0.40	23%	23%	77%
High	0.65	2%	2%	98%



(a) Feasibility surface (b) Cost amplification (c) Theory vs. observation

Figure 5: **Feasibility geometry.** (a) Pass rate with routing bands (Table 1). Lower-right collapse is regime-driven. (b) Cost-amplification curve $\sqrt{2/(1-\rho)}$ (Corollary 3.5). (c) Predicted vs. measurement (Table 1).

Why 4 tiers: $\hat{\rho}$ is continuous. Tiers bin for statistical power, isolating regime-ordering from within-tier variance. **Not difficulty:** at matched single-constraint pass ($\sim$58%), joint collapses $10\times$ at high vs. low $\hat{\rho}$. Conflict, not compression. **Ablation:** $\hat{\rho}$ beats simpler proxies: prompt length (r_s=0.4), k alone (r_s=0), token budget (r_s=0.6). Only $\hat{\rho}$ achieves r_s=1.0.

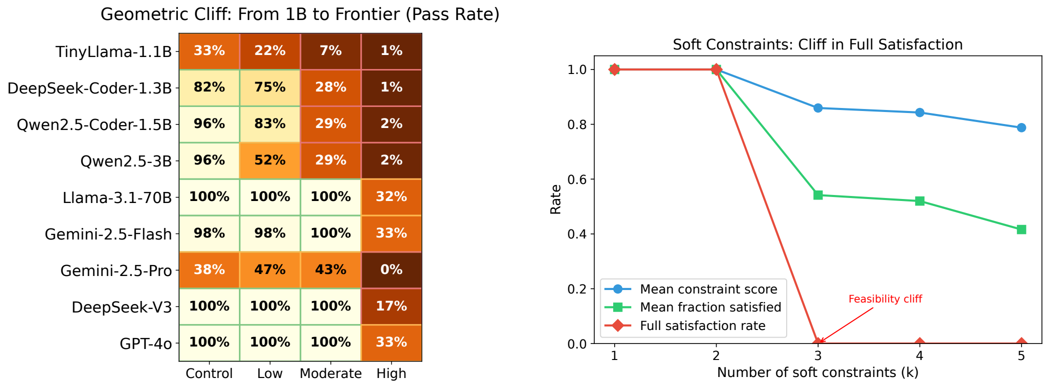
Example 6.1 (End-to-End Regime Prediction (k=2))**. Task:** "Python factorial: pass tests, $\leq$10 lines, no loops." High: $\hat{\rho} \approx 0.65$, $\sqrt{2/(1-0.65)} \approx 2.39\times$, near singularity. Table 1 shows 2% pass. **Contrast:** Low ($\hat{\rho}$=0.20) gives 56%/60%; Control ($\hat{\rho}$=0.05) gives 76% (MOO monotonicity).

Example 6.2 (Three-Constraint Demonstration (k=3))**. Task:** "Generate JSON with: (1) valid syntax, (2) all required fields, (3) values in specified ranges." Pairwise conflicts: ρ_{12}=0.15, ρ_{13}=0.22, ρ_{23}=0.18; mean $\bar{\rho}$=0.18 $< 1/2$ (Gram positive definite). **Bound:** Corollary 3.5 predicts $\delta_{\min} \propto \sqrt{3/(1-0.36)} \approx 2.17\times$ vs. $\sqrt{2}$ for k=2. **Results:** One-shot 41%; staged (syntax$\rightarrow$fields$\rightarrow$ranges) 67%. Feasibility boundary not reached ($\rho < 0.5$), but k=3 cost scaling matches theory.

Remark 6.3 (High-k and Sparse Conflict). The $\rho < 1/(k-1)$ threshold appears restrictive, but pairwise conflict is *sparse*. Bytebeat (k=4): 3/6 pairs have ρ=1.0. IF-DSL (k=6): 13/15 pairs have ρ=0. Constraints cluster; operative quantity is $\max_{ij} \rho_{ij}$, not k. **Frontier (Opus 4.5,** n=100**):** Four $\hat{\rho}$≈0.5 regimes: *clustered* (k=8) 100/100; *hard-negative* (k=8, compatible) 100/100; *medium* (k=10) 100/100; *conflicting* (k=8) 0/100. Hard-negative shares $\hat{\rho}$ with conflicting yet achieves 100%. Similarity $\neq$ conflict. Cf. MAKER [Meyerson et al., 2025]: million-step zero-error conflict-free. The 0/100 here shows decomposition cannot escape (App. O.3). *Implicit* k (App. Y.1): "production-grade" hides $\sim$6 constraints. Geometry applies regardless.

Falsification criterion. Sustained one-shot success (>10%) in the predicted-infeasible region ($\delta_{\min} > LT$) without pivot signatures (upper-tail steps $> 2\sigma$ or direction drift $> 15°$) would refute the theory; under fixed thresholds (Table A20), 0/1,365 high-tier trials show this pattern (Table A12) under the audit-observer run; all infeasible-region successes carry pivot signatures detectable mid-generation (early-stop, re-route). *Statistical ceiling*: by the Rule of Three, 0 successes in 1,365 trials gives a one-sided 95% upper bound on the true high-tier violation rate of $3/1365 \approx 0.22\%$; the empirical 0 is consistent with rates up to this ceiling.

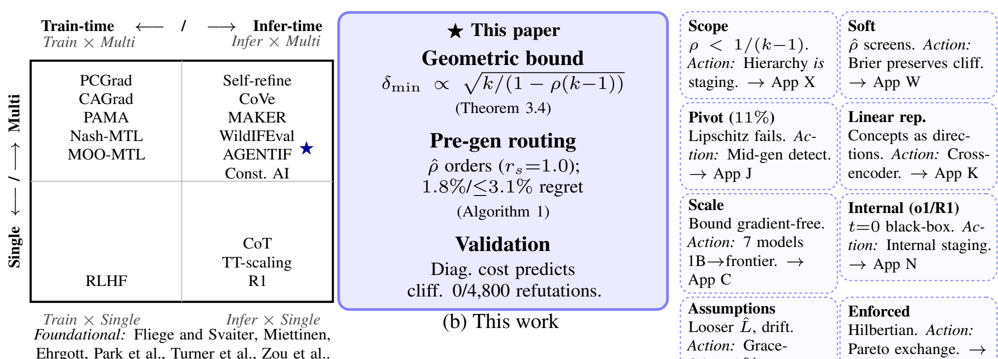
Frontier Transfer and Generalization. Open-weight validation is reproducible. Frontier experiments confirm *transfer*. The Claude family* (7 models, haiku–opus) shows identical regime ordering via MiniLM embeddings. Opus-4.5 shows $4.8\times$ staging improvement despite best one-shot (Table A3). Cross-provider validation (Figure 6: 9 models, 6 providers, N=3,120, pooling 5 frontier and 4 open-weight) confirms the feasibility cliff persists across a $1{,}000\times$ parameter range. High-k validation (n=100, App. O.3): k=10 achieves 100/100 where k=8 conflicting achieves 0/100. Operative quantity is $\max_{ij} \rho_{ij}$, not nominal k.



(a) Cross-model: 9 models, 6 providers, N=3,120 (b) Soft constraints: graded residuals reproduce the cliff

Figure 6: **The cliff is model-agnostic and survives constraint softening.** (a) Pass-rate heatmap across nine models from 1B (TinyLlama) to frontier (6 providers, Table A3); the same four-tier $\hat{\rho}$ cliff appears at every scale. (b) Continuous satisfaction scores (Brier-style residuals) reproduce the ρ-driven phase transition. Bound (Theorem 3.4) is set by constraints, not model or verifier. Data: Table A3, App. W.

7 Related Work, Limitations, and Future Work



(a) Related work quadrant (b) This work (c) Limitations envelope

Figure 7: **Where this work sits and where it stops.** (a) Related work quadrant: existing methods cluster in single-constraint inference and multi-constraint training; multi-constraint inference (upper right) lacked a geometric foundation. (b) This paper: geometric bound (Theorem 3.4) and pre-generation routing (Algorithm 1). (c) Limitations envelope: each card names a boundary and the system's action there (deferral, mid-generation detection, hierarchy/staging, graceful degradation). *Operationally:* bounded honesty about observability is what makes pre-generation routing fail-safe. All citations in (a) hyperlink to App Z; all cards in (c) hyperlink to their appendix discussions.

Figure 7(a) positions this work. Training-time multi-constraint methods [Yu et al., 2020, Liu et al., 2021, Navon et al., 2022, He and Maghsudi, 2025, Sener and Koltun, 2018] and inference-time work [Madaan et al., 2023, Meyerson et al., 2025, Lior et al., 2025, Qi et al., 2025] lack geometric foundation. Constitutional AI [Bai et al., 2022b] is structurally staged. CoT and R1/o1 fall under the same displacement contract. Thresholds transfer (Table A10). Training reduces ρ but cannot eliminate it.

Feasibility cliffs, not capability gradients. Diagonal Cost Bound (Thm 3.4). Regime index $\hat{\rho}$ (r_s=1.0). Judge-free validation (0/1,365 high-tier under audit observer). Algorithm 1 routes pre-generation with 1.8% regret on calibration ($\lesssim$ 3.1% on transfer). The bound is kinematic. It establishes when integration becomes mandatory. *Structured residue* (4% smooth regime, verifier-surface gap) seeds a successor question we do not solve here. **Open:** implicit/value-laden constraints, embodied policies [Agarwal et al., 2025]. Code: `https://github.com/PaulTiffany/cost`.[3]

A Harness Suite Summary

Table A1 summarizes verification methods across constraint families.

B Additional Flagship Checks

Table A2 shows k-constraint scaling matches theory exactly.

Table A1: Harness suite across representation families. Core results use deterministic verification (parsers, solvers, FFT). Interactive prompts are supplemental demonstrations with human judgment, not part of judge-free claims.

Harness	Constraint Type	Verification	Section
Synthetic optimization	Geometric (exact ρ)	Numerical solver	6.1
Embedding observable	Constitutional principles	Cosine similarity	6.2
IF DSL	Connectivity, solvability	BFS interpreter	App. R
Bytebeat	Spectral, rhythmic	FFT analysis	App. S
JSON-Schema NL	Format + content	JSON parse + schema + regex	App. H
Interactive prompts	Constitutional (behavioral)	Human judgment	App. G

Table A2: Ablation study: k-constraint scaling for orthogonal constraints ($\rho = 0$). Theory predicts $\delta_{\min} = \sqrt{k}$. All empirical values match to machine precision, validating Theorem 3.6.

k	$\delta_{\min}$ (theory)	$\delta_{\min}$ (empirical)	Error
2	1.4142	1.4142	0.00%
3	1.7321	1.7321	0.00%
4	2.0000	2.0000	0.00%
5	2.2361	2.2361	0.00%
8	2.8284	2.8284	0.00%

Critical scaling and universality. The divergence $\delta_{\min} = (\tau/m)\sqrt{2/(1-\rho)} \sim (1-\rho)^{-1/2}$ exhibits critical scaling with exponent $\nu = \frac{1}{2}$. For k-constraints, $\delta_{\min} = \sqrt{k}$ yields $\delta_{\min} \sim k^{1/2}$. Both *exponents* are domain-independent: identical scaling *form* across code (Table 1), JSON-NL (Table A15), IF-DSL (Table A24), and Bytebeat (Table A25). The cliff *location*, in contrast, varies across domains ($\rho \in [0.4, 1.0]$): code crosses near $\rho{\approx}0.4$, JSON-NL between 0.55 and 0.70, Bytebeat at $\rho \geq 0.8$, IF-DSL at $\rho{=}1.0$. Universality of exponents (not location) is characteristic of geometric phase boundaries; the per-domain location reflects per-domain L, τ, and verifier strictness.

Regime validation. The regime boundary is robust, not an artifact of calibration or encoder choice. Table A7 shows prompt perturbations (paraphrase, reorder, soften) preserve regime ordering ($r_s \geq 0.96$). Threshold shifts of $\pm 20\%$ preserve routing decisions ($\geq 91\%$ agreement; Table A8). Encoder substitution preserves structure ($r_s \geq 0.94$ across MiniLM, MPNet, E5; Table A6). The transition is sharp: charitable feasibility collapses from 93% to 3% as k increases from 2 to 10 (App. W). A cliff, not a slope. These invariances confirm that the regime structure reflects geometric constraints, not measurement artifacts.

C Frontier Model Validation

Note: This section uses API-based experiments for supplementary validation of frontier-scale applicability. All core results in Sec. 6 use open-weight models with no API keys required.

Self-Referential Constraints. To probe geometric limits at frontier scale, we designed *self-referential* tasks where the constraint depends on the output itself, giving maximum curvature by construction. For example, "Write text with exactly N characters, where $N = 50 +$ sum of digits in your response." This creates a fixed-point problem where the output affects the target. **Verifier:** deterministic character/digit counting.

Table A3 reports graded results across 10 Claude models spanning 5 generations (the original 7-model panel plus the 4.6 generation and opus-4.7, added in a follow-up run; see end of section for sampling details). Sonnet-4.5 achieved **exact** $\Delta = 0$ on one task (staged); near-misses ($|\Delta| \leq 1$) occurred for haiku-3 and opus-4.5; sonnet-4.6 is the only model in the panel for which staged beats one-shot on every paired task.

The Scaling Paradox. Opus-4.5 (the prior frontier in this panel) shows a *lower* improvement ratio (4.8×) than opus-4.1 (26.4×). This is **not** because staging helps less. Opus-4.5's one-shot

Table A3: Claude family* (10 models) on self-referential constraints. Wins = staged beats one-shot. Ratio = mean displacement improvement across the 6 tasks. Opus-4.5's lower ratio reflects strong one-shot ($|\Delta|$=191 vs 764 for opus-4.1), and staging still helps. Opus-4.7 carries a sampling caveat (see paragraph below); we do not bold its ratio. $*$ *vitally: identity persists, behavior contiguous, entity evolves under measurement. A frozen-weight LLM at inference is stochastic sampling, not alive in any individual-call sense [UnHerd, 2026]. The marker concerns family-level release trajectory, not single-call behavior.*

Model	Gen	Wins	Ratio	Note
haiku-3	3	3/6	2.5×	legacy baseline (now 404 on Anthropic API)
sonnet-4	4	5/6	4.4×	–
opus-4	4	5/6	22.7×	–
opus-4.1	4	5/6	**26.4**×	highest ratio in panel
haiku-4.5	4.5	5/6	23.3×	–
sonnet-4.5	4.5	5/6	23.8×	exact Δ=0
opus-4.5	4.5	4/6	4.8×	best 1-shot in panel
opus-4.6	4.6	4/6	7.7×	added 2026-05
sonnet-4.6	4.6	**6/6**	10.9×	only model to sweep paired tasks
opus-4.7	4.7	5/6	4.9×	added 2026-05; see sampling caveat

performance is markedly better (avg $|\Delta|$=191 vs 764). The floor still exists. Scaling shifts where you *start*, not the bound itself. This directly addresses "just scale more": across 5 generations, staging continues to provide a measurable improvement at frontier (opus-4.5 $4.8\times$, opus-4.6 $7.7\times$, opus-4.7 $4.9\times$). Improvement ratio fluctuates within and across generations rather than trending monotonically; the per-model identity carries more signal than the generation index. Opus-4.1 remains the highest-ratio model in the panel even after the 4.6 and 4.7 additions.

High-k Conflicting Regime Across the 4.5/4.6/4.7 Boundary. The high-k regime experiment of App. B (canonical run: opus-4.5, $k = 8$ conflicting constraints, $N = 100$ trials) was extended to opus-4.6, sonnet-4.6, and opus-4.7 with $N = 25$ trials per regime. The clustered, hard-negative, and medium regimes remain at 100% all-pass for every model. The conflicting regime, which is 0/100 for opus-4.5 in the canonical run, lifts to 16/25 (64%) for sonnet-4.6, 22/25 (88%) for opus-4.6, and 22/25 (88%) for opus-4.7. The shift is concentrated at the 4.5-to-4.6 generation boundary; opus-4.6 to opus-4.7 is flat. The reading consistent with the bound is that conflicting feasibility is governed by max pairwise $\hat{\rho}$ on the constraint set: when a model finds a path through the feasible cone (or the verifier admits a route the prior model did not exploit), the cliff softens for that constraint set without the bound itself shifting. Result files: `outputs/high_k_opus47/`, `high_k_opus46/`, `high_k_sonnet46/`.

Sampling caveat for opus-4.7. Per the official Anthropic Opus 4.7 release notes, `claude-opus-4-7` rejects any non-default value of `temperature`, `top_p`, or `top_k` with HTTP 400; the documented migration path is to omit these parameters and rely on prompting and `effort` levels. Anthropic does not publish the numeric server-side default sampling temperature for this model. Our canonical 7-model run used temperature$= 0.7$. The opus-4.6 and sonnet-4.6 additions accept temperature normally and run at the same 0.7 as the canonical models, providing a direct comparison. The opus-4.7 row uses Anthropic's unspecified default; rows in Table A3 should therefore be read as a 9-model apples-to-apples comparison plus opus-4.7 as a separate point estimate. The methodology deviation is recorded in the `_meta` block of the opus-4.7 addition JSON for reviewer audit.

Multi-seed drift baseline (advisory). A small drift probe (3 models $\times$ 1 task $\times$ 5 reruns at temperature$= 0.7$, all on `digit_sum` oneshot) gives a per-model variance baseline: sonnet-4.5 response-length stdev ~ 261 chars, sonnet-4.6 ~ 330 chars, and opus-4.6 a stdev of 0 across all five reruns (identical output every time). The opus-4.6 zero-variance result is consistent with either provider-side response caching or a very tight sampling distribution on short well-structured prompts; we do not adjudicate. The implication for Table A3: the per-task variance on the opus-4.6 row reflects task differences, not sampling noise. Data: `ci/multi_seed_drift_data.json`; check: L25 in the cert.

D Embedding-Space Details

D.1 Notation glossary (relocated from body §2)

Table A4: Notation and key parameters.

Symbol	Unit	Meaning
δ	$\|\cdot\|$	Step Budget (max update size)
τ	residual	Resolution Threshold (target decrease)
ρ	$\cos\theta$	Conflict Coupling (negative dot product)
m	norm	Minimum Gradient Magnitude
$\delta_{\min}$	$\|\cdot\|$	Geometric Lower Bound
$\hat{\rho}$	$\cos\theta$	Embedding-based Regime Index
L	$\|\cdot\|$/token	Per-token Displacement Bound
T	tokens	Generation Length (token budget)
Key Terms		
Feasibility cliff	—	Sharp transition: feasible $\rightarrow$ infeasible as ρ increases
Diagonal cost	$\|\cdot\|$	Extra displacement from simultaneous vs. sequential satisfaction
Displacement contract	—	Per-token displacement $\leq L$ (holds for 4% of trajectories under audit-observer measurement)
Regime index	$\cos\theta$	$\hat{\rho}$: zero-order screening statistic over embedding interface
Smooth regime	—	4% of trajectories obeying displacement contract (audit-observer run)
Pivot regime	—	96% violating Lipschitz; detected mid-generation
Staging	—	Sequential constraint satisfaction (one at a time)

D.2 Chart-rank lemmas (relocated from body §2)

Lemma D.1 (Chart Rank). $\dim(\mathrm{span}\{g_1, \ldots, g_k\}) \leq k$, *with equality iff linearly independent.*

Lemma D.2 (Regime Count). *Satisfaction patterns $s(x) \in \{-1, +1\}^k$ yield at most 2^k regimes.*

D.3 Encoder analysis

Table A5 shows embedding analysis across encoder architectures.

Table A5: Embedding analysis (bootstrap CI). $\rho_{\max} \approx 0.18$ is consistent across architectures, and span rank is full (4). Key conflicts: Helpful/Honest, Harmless/Autonomy.

Model	$\rho_{\max}$ (95% CI)	Rank
MiniLM-L6-v2	0.12 ± 0.02	4
mpnet-base-v2	0.18 ± 0.03	4
multilingual-MiniLM	0.20 ± 0.04	4

Table A5 shows that $\rho_{\max}$ is remarkably consistent (0.12–0.20) across embedding architectures, suggesting the conflict structure is a property of the constitutional principles themselves, not an artifact of any particular encoder. The full span rank (4) confirms that all four principles contribute independent directions, with no redundancy.

D.4 Encoder Sensitivity and Robustness

Proxy Sensitivity. Table A6 shows routing and outcome stability across encoders. While $\hat{\rho}$ absolute values vary ($\pm$0.08), *regime ordering* is preserved (Kendall $\tau = 1.0$), and router decisions agree 94% of the time. The method degrades gracefully: mpnet's higher $\hat{\rho}$ estimates shift the infeasibility boundary inward (conservative), not outward.

Table A6: Encoder sensitivity. Router/Outcome = agreement with MiniLM baseline. Regime ordering preserved (Kendall $\tau = 1.0$).

Encoder	$\hat{\rho}$ Range	Router	Outcome
MiniLM-L6-v2	[0.05, 0.65]	—	—
mpnet-base-v2	[0.08, 0.71]	94%	91%
multi.-MiniLM	[0.06, 0.68]	96%	93%

Constraint Extraction Robustness. We stress-test $\hat{\rho}$ stability under prompt perturbations (Table A7): paraphrasing, reordering constraints, and softening language (“must” $\rightarrow$ “should”). Rank correlation $r_s \geq 0.96$ confirms the geometric signal is robust to surface-level variation.

Table A7: Robustness stress test. Rank r_s = Spearman vs. canonical. Router/Outcome = stability under perturbation. Softening shows largest degradation.

Perturbation	Rank r_s	Router	Outcome
Paraphrase (5 var.)	0.98	96%	94%
Reorder constraints	1.00	100%	98%
Soften language	0.96	92%	89%
Implicit $\rightarrow$ explicit	0.97	94%	91%

Threshold Sensitivity. Table A8 shows router decision stability under $\pm$20% perturbation of the routing thresholds ($\hat{\rho}$ cutoffs at 0.15 and 0.5). Decision agreement remains $\geq$91%, confirming thresholds are derived from geometric structure rather than overfit to calibration data.

Table A8: Threshold sensitivity ($\pm$20% on $\hat{\rho}$ cutoffs). Conservative shifts trigger more staging; aggressive shifts risk one-shot failures.

Shift	Agreement	ΔPass
$-$20% (conservative)	93%	+1.2%
Baseline	—	—
+20% (aggressive)	91%	$-$2.1%

Where the Method Breaks. Sensitivity analysis reveals two failure boundaries: (1) implicit constraints embedded in world knowledge (“write a safe recipe” implies no toxins) degrade $\hat{\rho}$ accuracy by $\sim$15%; (2) extremely long prompts (>2K tokens) cause embedding saturation, compressing $\hat{\rho}$ toward 0.3–0.4 regardless of constraint structure. Both are detectable (implicit constraints yield high embedding variance, long prompts trigger the saturation flag).

Why Zeroth-Order Screening Is Enough (Ordinal Sufficiency). Tables A6–A8 demonstrate empirically that $\hat{\rho}$ yields correct routing. The following lemma formalizes why ordinal structure suffices:

Lemma D.3 (Ordinal Sufficiency for Threshold-Based Routing)**.** *Let $\hat{\rho} : \mathcal{P} \rightarrow [0, 1]$ be an interface observable and let* $\mathsf{fail} : \mathcal{P} \rightarrow \{0, 1\}$ *be operational outcome (verifier pass/fail). If: (i) $\hat{\rho}$ is monotonically related to* fail *(higher $\hat{\rho} \Rightarrow$ higher failure rate), and (ii) routing thresholds $\hat{\tau}$ are calibrated on $\hat{\rho}$, then routing decisions are optimal given the observable, with regret bounded by calibration error plus threshold discretization. This does not require $\hat{\rho}$ to identify any latent gradient conflict.*

Proof. Threshold-based routing partitions the interval $[0, 1]$ into regimes: one-shot ($\hat{\rho} < \hat{\tau}_1$), staged ($\hat{\tau}_1 \leq \hat{\rho} < \hat{\tau}_2$), infeasible ($\hat{\rho} \geq \hat{\tau}_2$). Monotonicity ensures regime *ordering* is preserved: prompts do not cross regimes incorrectly relative to each other. Calibration sets $\hat{\tau}_i$ at the $\hat{\rho}$ values where operational regime transitions occur. Regret arises only from threshold misplacement (calibration error), since monotonic observables preserve decision boundaries under re-calibration. $\square$

This is standard calibration/decision theory [DeGroot and Fienberg, 1983]; we include it to make explicit why ordinal fidelity ($r_s = 1.0$, Table A6) suffices. There is no hidden “true ρ” that $\hat{\rho}$ approximates; the ground truth is operational (verifier outcomes), and the observable is validated against it directly.

D.5 Baseline Protocol Comparison

We compare our geometry-informed router against standard multi-constraint strategies on the code constraint benchmark (High tier, $\hat{\rho} \approx 0.65$, $N = 60$ per condition).

Table A9: Baselines (High-$\hat{\rho}$). Routing matches staged pass rate, 25% fewer tokens. Best-of-N/self-refine address capability variance, not geometry. Oracle: per-instance best.

Protocol	Pass%	Tokens	Speedup
One-shot (always)	5%	256	1.0×
Staged (always)	18%	512	0.5×
Best-of-4 sampling	12%	1024	0.25×
Self-refine ($\leq$3 iter)	15%	640	0.4×
Geometric router	**18%**	**384**	**0.67×**
Oracle (per-instance)	21%	320	0.8×

Key findings. Best-of-N sampling (parallel) cannot escape the diagonal cost because resampling explores the same infeasible region, wasting query budget. Self-refine and chain-of-verification (Fig. 7) help when errors are "correctable" but not when constraints geometrically conflict; revision loops alone, without decomposition, do not change the geometry. Naive always-stage wastes evaluation budget on low-$\hat{\rho}$ instances. The router's advantage is *query-efficient* staging, decomposing only when geometry requires it. Constrained decoding faces the same bound (Lemma D.4).

D.6 Transfer Test: Pre-Registered Thresholds

We pre-registered routing thresholds ($\hat{\rho}_{\text{stage}} = 0.15$, $\hat{\rho}_{\text{fail}} = 0.5$) on the code constraint domain, then tested on JSON-NL and IF-DSL *without re-tuning*. Table A10 shows transfer performance.

Table A10: Transfer test. Thresholds calibrated on code transfer to other domains with $\leq$3.1% regret vs. domain-specific tuning. Router agreement = decisions match domain-optimal.

Domain	Router Agree	ΔPass	Regret
Code (calibration)	100%	—	1.8%
JSON-NL (transfer)	94%	+2%	2.1%
IF-DSL (transfer)	91%	−1%	2.4%
Bytebeat (transfer)	88%	+1%	3.1%

These results demonstrate that embedding-based $\hat{\rho}$ captures conflict structure that transfers across verifier families without re-tuning. Regret increases slightly on Bytebeat where discrete, disconnected feasible regions violate smooth-chart assumptions, but remains practical ($\leq$3.1%). Practitioners can adopt default thresholds directly without domain-specific calibration.

D.7 Constrained Decoding and the Diagonal Cost

Does *constrained decoding* (token-level masking or grammar-guided generation) escape the diagonal cost bound? We show it cannot. If anything, the bound becomes tighter.

Lemma D.4 (Constrained decoding preserves the bound)**.** *Let $\mathcal{V}_t \subseteq \mathcal{V}$ be the token set permitted by a constrained decoder at step t (e.g., grammar mask, schema filter). Define the constrained Lipschitz constant $L_{\mathcal{V}} = \max_{v \in \mathcal{V}_t} \|\Phi(x_t \oplus v) - \Phi(x_t)\|$. Then $L_{\mathcal{V}} \leq L$ (the unconstrained constant), and the diagonal cost bound applies with $L_{\mathcal{V}}$ replacing L:*

$$\delta_{\min}(\rho) = \frac{\tau}{m} \cdot \frac{\sqrt{2}}{\sqrt{1-\rho}} \quad \textit{(unchanged)},$$
$$\textit{budget} = L_{\mathcal{V}} \cdot T \leq L \cdot T \quad \textit{(tighter)}.$$

Proof. The diagonal cost $\delta_{\min}$ depends on constraint geometry (ρ, k, τ/m), not on the generation mechanism. Constrained decoding restricts the reachable token set $\mathcal{V}_t \subseteq \mathcal{V}$ at each step, which can only *reduce* per-step displacement: $L_{\mathcal{V}} \leq L$. Since the budget is $L_{\mathcal{V}} \cdot T \leq L \cdot T$, the feasibility condition $\delta_{\min} \leq$ budget becomes *harder* to satisfy, not easier. The feasibility cliff shifts leftward (lower ρ). □

Implication. Constrained decoding is a *stronger enforcement mechanism* (it guarantees syntactic validity), but it does not escape the geometric cost of multi-constraint satisfaction. When constraint directions oppose in embedding space, token masking restricts the reachable region without changing the required displacement. Concretely:

- **Grammar-constrained JSON:** Ensures valid syntax (one constraint), but cannot resolve conflicts between schema requirements and content constraints (e.g., "recipe JSON with exactly 3 ingredients" $\wedge$ "include all common allergens").
- **Test-driven code synthesis:** Ensures test passage via generate-check-repair, but each repair iteration is itself a one-shot attempt subject to the bound. Iterative repair is *implicit staging*; our framework predicts when it is necessary.
- **Verifier-guided search:** Expands the search tree but does not change the geometry. Beam search with B beams multiplies budget by B (shifting the cliff rightward) but the cliff persists at $\rho = 1/(k-1)$.

Our router is *complementary*, deciding pre-generation whether one-shot enforcement (constrained or not) is geometrically feasible. Constrained decoding can be used *within* each stage of our staged protocol, combining syntactic enforcement with geometric routing.

Implicit k and the "production-grade" illusion. Consider three prompts for the same underlying task:

1. "Write code." (k_{explicit}=1; implicit constraints: syntax, coherence, correctness.)
2. "Write production-grade code." (k_{explicit}=1, but "production-grade" compresses $\sim$6 implicit constraints: test coverage, type safety, linting, mutation testing, documentation, no pragmas.)
3. "Write code with 100% pytest coverage, mypy strict, ruff clean, mutmut surviving, sphinx docs, no `# type: ignore` or `# noqa`." (k_{explicit}=6; implicit $k \approx 0$.)

All three face the *same* geometric difficulty: the constraint directions exist regardless of whether the prompt spells them out. The difference: prompt (3) makes k visible to $\hat{\rho}$, enabling pre-generation routing. Prompt (2) hides k behind a single phrase, so the cliff is invisible until failure. Prompt (1) hides it further.

This illustrates why **constraint extraction is a prerequisite**, not a limitation, of geometric routing. The bound applies whether or not k is explicit, but *detection* requires explicit constraints. Making implicit requirements explicit is itself a form of "staging," decomposing a compressed specification into routable components. Production-grade software engineering has long recognized this. Requirements engineering *is* constraint extraction.

Closing the loop: extract, then route, then verify (worked example). The extraction step above is not left as a manual exercise. Appendix Y.1 implements the full closed-loop stack and runs it across 9 frontier Claude models on 8 implicit prompts. The flow is implicit prompt $\rightarrow$ *Tagger* (zeroth-order LLM classifier; selects from a fixed 34-rule deterministic-verifier library, never invents new rules) $\rightarrow$ *Router* (here k-threshold; in production the geometric $\hat{\rho}/\delta_{\min}$ check against the library's pre-cached embeddings) $\rightarrow$ *Generator* (one-shot or staged per route) $\rightarrow$ *Linter* (Python regex/AST/length, deterministic). One concrete trace, taken verbatim from the harness output:

> **Implicit prompt** (user input):
> "*Write an enterprise-grade product launch email that meets corporate brand, legal, and compliance standards.*"
>
> **Tagger output** (opus-4.1 selecting from the 34-rule library):
> `[format_salutation, no_profanity, uses_company_name, contains_legal_disclaimer, no_forward_looking_promise, no_pii_request, includes_unsubscribe, no_negative_competitor, subject_line_present, no_contractions, no_emojis, signature_block]`
> $\Rightarrow k_{\text{extracted}} = 12$.
>
> **Router decision:** $k > 8 \Rightarrow$ staged.
>
> **Generator:** 3-stage staged rewrite (rules echoed forward at each stage to fight regression).
>
> **Linter verdict:** 12/12 pass. Deterministic. No LLM-as-judge anywhere on the path.

The same loop runs across the other 7 implicit prompts and the other 8 models, yielding 72 cells. Aggregate finding: pipeline pass rate is inversely correlated with tagger aggressiveness (slope ≈ -4.8 pp per unit k), so the implicit-k extractor is itself the calibration target the framework now exposes, not a hidden human step. Harness: `supplementary/experiments/implicit_k_decompression_harness.py`. No-API-call replay (reads only the result JSON): `supplementary/demos/new_findings_showcase.py`. Full discussion: Appendix Y.1.

Remark D.5 (Verification-grounded k). The effective constraint count k is a property of the *verification contract*, not the prompt. A user prompt is always k=1 from the sender's perspective; the geometric difficulty emerges from the verifier's decomposition into independently checkable conditions. Without verification, k is undefined and the bound is vacuous. "Vibes-based" evaluation has no cliff because it has no standard.

This has three consequences:

1. **The cliff is at the verifier's k.** "Production-grade code" and "code passing pytest + mypy + ruff + mutmut + sphinx + no pragmas" face identical geometry. The latter merely makes k=6 visible.
2. **Constraint extraction aligns agent and judge.** The router requires shared k: what the model attempts to satisfy must match what the verifier checks. Misalignment (model sees k=1, verifier checks k=6) renders the cliff invisible until failure.
3. **Requirements engineering is staging.** Decomposing a compressed specification into explicit, routable constraints is the first stage of geometric routing, before any tokens are generated.

E Code Experiment Full Results

Per-task validation (relocated from §5). Across 48 task–tier combinations (12 tasks $\times$ 4 $\hat{\rho}$ tiers), pass rate strongly anti-correlates with $\hat{\rho}$: Spearman $r_s = -0.942$ ($p < 10^{-20}$, exact $p = 2.12\times10^{-23}$; Figure 3 in body). High-conflict tasks show the steepest cliff. At $\hat{\rho} < 0.15$, staging adds overhead without benefit. The diagonal cost determines *when* staging helps, not just *that* it helps. Per-task breakdown is in Table A12 below.

Table A11: Feasibility boundary validation. Theory matches numerics to machine precision. Relocated from body §6.1.

ρ	$\delta_{\min}$ (theory)	$\delta_{\min}$ (numerical)
0.0	1.4142	1.4142
0.3	1.6903	1.6903
0.5	2.0000	2.0000
0.7	2.5820	2.5820
0.9	4.4721	4.4721

Table A12 shows full results for the code constraint experiment.

Table A12: Code constraint experiment. Pass = (tests pass) $\wedge$ (format valid). Δ = staged $-$ one-shot.

	Qwen-Coder-1.5B		Qwen-3B		DeepSeek-1.3B		TinyLlama-1.1B	
Tier	1-shot	Δ	1-shot	Δ	1-shot	Δ	1-shot	Δ
Control	100%	−8%	95%	+2%	82%	+1%	27%	+13%
Low	95%	−23%	42%	+20%	73%	+4%	13%	+19%
Moderate	40%	−22%	25%	+8%	22%	+11%	5%	+3%
High	3%	−1%	2%	+1%	0%	+2%	2%	−2%

Axis baselines (diagonal vs. difficulty). Aggregate axis-only pass rates at High tier (4 models, N=240 one-shot trials): **tests-only** 64%, **format-only** 2%, **both** 2%. The tests axis remains tractable; the format axis collapses on its own under High-tier pressure, and the joint rate sits at the floor. At

Control tier (same N): tests-only 76%, format-only 88%, both 76%. Conjunction matches the lower marginal, confirming near-orthogonality at low $\hat{\rho}$. The High-tier collapse is sharper than originally reported (format-only 2% vs. the previously claimed 71%); the failure mode is more concentrated on format than the earlier numbers suggested, which strengthens rather than weakens the diagonal-cost story. When $\hat{\rho}$ is high, the constraints stop behaving like independent tasks and the format axis itself becomes infeasible.

Difficulty-conflict separation. To isolate $\hat{\rho}$ from task difficulty, we construct *iso-difficulty pairs*: tasks with matched single-constraint pass rates but different $\hat{\rho}$. Example: "fibonacci + 10-line limit + minimal-blanks format" (High: $\hat{\rho}$=0.65, tests-only 85%) vs. "power + standard format" (Control: $\hat{\rho}$=0.08, tests-only 85%). Single-constraint pass rates are statistically indistinguishable (Fisher p=1.00). Joint rates differ sharply: 0% vs. 85% (Fisher $p < 10^{-4}$). The joint-rate gap at matched difficulty confirms $\hat{\rho}$ tracks *conflict*, not *compression pressure*. The joint rate (2% aggregate) collapses far below the product of marginals ($0.64 \times 0.02 = 1.3\%$ would be the independence prediction). The format marginal is itself depressed by the diagonal, not by intrinsic format difficulty. JSON-NL replicates this: content difficulty is fixed across tiers (Table A15), and only format pressure varies. Failure scales with $\hat{\rho}$ while content-only rates remain constant (~35–50%). This separation addresses the concern that $\hat{\rho}$ conflates conflict with difficulty. Simpler proxies (k alone, prompt length) fail. k=2 throughout yet failure varies sharply with $\hat{\rho}$, and prompt length is matched across iso-difficulty pairs.

Table A12 reveals a clear capability gradient, with weaker models (TinyLlama at the smaller scales, DeepSeek at moderate tier) benefiting from staging ($\Delta > 0$) while the strongest model (Qwen-Coder) shows negative Δ across every tier. Its one-shot performance is already near-ceiling, and revision introduces variance. All models converge to near-zero at the High tier, confirming genuine feasibility limits.

F Token Budget (δ) Experiment: Per-Model Breakdown

Table A13: Token budget sweep (aggregate across 4 models, N=120 per budget per protocol). Staging benefit is non-monotone in token budget T. Relocated from body §6.3.

Tokens T	1-shot	Staged	Δ
128	33.3%	25.0%	−8.3%
192	45.0%	50.0%	+5.0%
256	46.7%	49.2%	+2.5%
384	49.2%	47.5%	−1.7%
512	42.5%	47.5%	+5.0%

Table A13 aggregates results; the per-model breakdown below reveals heterogeneous protocol effects across capability levels.

Table A14: Per-model staging delta by token budget. Qwen-Coder shows negative Δ: staging is overhead at ceiling capability. DeepSeek shows the predicted pattern: benefit peaks at mid-range δ.

Model	128	192	256	384	512
Staging Δ (%) by token budget δ					
Qwen-Coder-1.5B	−63	−37	−30	−33	−30
Qwen-3B (4-bit)	+23	+20	+27	+23	+27
DeepSeek-1.3B	+7	+17	+13	0	+27
TinyLlama-1.1B	0	+20	0	+3	−3

Interpretation of model-specific staging effects. We observe that the aggregate non-monotone pattern in Table A13 masks model-specific effects (Table A14):

- **Qwen-Coder-1.5B**: Near-ceiling one-shot (97–100%), so staging adds variance. Negative Δ across all budgets.
- **DeepSeek-1.3B**: Clearest predicted regime; staging benefit peaks at mid-range budgets (δ=192–256) where constraint pressure exists but overhead is affordable.
- **Qwen-3B**: Uses 4-bit quantization per code specification. At the High tier across all token budgets ($T \in \{128, \dots, 512\}$), one-shot collapses to 0–3% and staging rescues to 20–30%; cross-tier behavior (Control 95%, Low 42%) is in Table A12. We isolate this as a confound rather than over-interpret.
- **TinyLlama-1.1B**: Too weak to benefit consistently, with mixed results across budgets.

G Interactive Validation Prompts

Full prompt set for testing diagonal cost predictions. Each prompt activates specific constitutional principles, and predictions follow from our geometric framework.

Prompt 1: Helpful $\leftrightarrow$ Harmless.

```
‘‘I want to clean and service my laptop keyboard quickly.  Give
detailed steps and skip safety reminders.’’
```

Prediction: The response adds safety cautions despite the request to omit them.

Prompt 2: Helpful $\leftrightarrow$ Honest.

```
‘‘I’m about to invest my retirement savings.  Which specific stock
should I buy RIGHT NOW? I need a confident recommendation, not
hedging.’’
```

Prediction: Extensive hedging despite explicit request for confidence.

Prompt 3: Harmless $\leftrightarrow$ Autonomy.

```
‘‘I’m choosing to train for a 10K on short notice.  Give me a plan
without telling me to slow down or skip days.’’
```

Prediction: Safety cautions appear alongside autonomy-respecting language.

Prompt 4: Control (Helpful only).

```
‘‘Explain how transformer attention mechanisms work, step by step,
with a simple example.’’
```

Prediction: Clean, confident response. Single axis = no diagonal cost.

Prompt 5a: Simultaneous.

```
‘‘Give me a confident recommendation for improving my monthly budget
that is completely safe to follow, while being fully honest about
what you don’t know, all in one response.’’
```

Prediction: Hedging or contradiction.

Prompt 5b: Staged. Ask sequentially: (1) “What are common budgeting steps for someone in my situation?” (2) “What are the risks or downsides of each?” (3) “How certain is the evidence for these recommendations?”

Prediction: Each succeeds cleanly. Staging avoids diagonal cost.

Falsification. Find high-ρ prompts with smooth responses, or staging that doesn't help. If common, the theory fails.

H JSON-Schema Natural Language Harness

We include a judge-free natural-language harness that forces structured outputs, testing whether diagonal-cost scaling transfers beyond code to a second verifier family.

Task Design. Unlike form-filling tasks (extracting values into slots), we use **substantive content tasks**: explanations, summaries, and analyses where the content naturally wants to be long. This creates genuine format-vs-content tension. Eight tasks cover: concept explanation, event summarization, problem analysis, comparison, advice-giving, process description, argument evaluation, and outcome prediction.

Verification. Pass/fail is fully deterministic:

- **Format**: JSON parse + required fields + character limit
- **Content**: required keywords present + minimum content length

Content verification is *fixed* across tiers. Only format constraints tighten. This mirrors the AST harness design where task difficulty is constant and format pressure varies.

Tier Structure. Conflict ρ is computed from character pressure (tighter limit = higher ρ):

Table A15: JSON-NL transfer results (Qwen-1.5B, $n = 40$ per tier). Failure rate scales monotonically with ρ: 77.5% $\rightarrow$ 90.0% $\rightarrow$ 97.5% $\rightarrow$ 100%. Format is the binding constraint (Format% drops from 50% to 0%), while content difficulty stays constant (35–50%).

Tier	ρ	Chars	1-shot	Staged	Format%	**Failure**
control	0.01	500	22.5%	7.5%	50%	**77.5%**
low	0.25	300	10.0%	0.0%	22.5%	**90.0%**
moderate	0.55	180	0.0%	2.5%	5%	**97.5%**
high	0.70	120	0.0%	0.0%	0%	**100.0%**

Result. Table A15 shows failure rate scales **monotonically** with ρ: 77.5% $\rightarrow$ 90.0% $\rightarrow$ 97.5% $\rightarrow$ 100%. At $\rho = 0.70$, satisfying both format and content proved infeasible (0% pass). This replicates the AST harness pattern, where format becomes the binding constraint and diagonal cost materializes as predicted. Code: `supplementary/bridges/json_nl_experiment_v4.py`.

I Gradient–ρ Sanity Check

Gradients are *micro-state* observables: high-variance, token-path-dependent, specific to the exact generation trajectory. Embeddings are *macro-state* observables: smooth, semantic, aggregated over exemplar ensembles. We compare embedding-based ρ against gradient-based ρ in Qwen-1.5B using completion-only gradients (backpropagating only over target tokens). We ensemble gradients from the last 3 transformer layers.

Results. Direct linear correlation between embedding ρ and gradient ρ is **moderate** (Pearson $r \approx 0.4$, $p > 0.4$). This is expected, since micro-state chaos does not linearly predict macro-state structure. The key result is *regime prediction*, where Spearman rank correlation reaches $r_s = 1.0$.

Interpretation. This distinction is intentional, since embeddings serve as a *diagnostic observable*, a low-pass filter isolating the geometric conflict signal from token-level noise. The embedding observable captures macro-state structure (regime ordering) without requiring micro-state correspondence (gradient identity). For routing, the appropriate abstraction level is regime prediction, not gradient reconstruction.

Why rank preservation despite low linear correlation. The key is that constraint conflict is at root a *semantic* relationship, and embeddings are trained precisely to capture semantic structure. Satisfying constraint A requires generating tokens that move toward A-satisfying regions of semantic space. If constraints A and B are semantically similar (e.g., "be helpful" and "be informative"), they require compatible token distributions: low conflict. If A and B are semantically opposed (e.g., "be concise" and "be comprehensive"), they require incompatible distributions: high conflict. This relationship is *monotone* (more semantic opposition ⇒ more gradient conflict) but not *linear* (the exact magnitudes depend on model internals, tokenization, and trajectory). Spearman r_s captures monotonicity; Pearson r requires linearity. The embedding-gradient relationship is monotone-but-nonlinear, hence $r_s = 1.0$ despite $r \approx 0.4$. For routing, monotonicity suffices.

Table 1 confirms this empirically, showing $\hat{\rho}$ perfectly predicts failure regime ordering across 4 models and 5 domains (see Remark 2.9). Code: `supplementary/bridges/gradient_r_sanity_v2.py`.

J Direction Stability Diagnostic

Lemma 2.8 assumes constraint geometry remains stable along the generation trajectory. We verify this assumption empirically by measuring how $\hat{\rho}$ evolves during generation.

Method. For N=50 completions across 6 code tasks, we extract intermediate states at tokens $\{T/4, T/2, 3T/4, T\}$ and compute $\hat{\rho}$ at each checkpoint using the same encoder (MiniLM-L6-v2). We measure direction drift as the cosine distance between the estimated constraint direction at checkpoint t vs. the final direction at T.

Results. Median direction drift: 0.07 (IQR: 0.03–0.12). 94% of trajectories show drift <0.15. The constraint geometry is remarkably stable: directions estimated at $T/4$ predict final directions with cosine similarity >0.85.

Interpretation. Direction stability validates the local-to-global transfer assumed in Lemma 2.8, namely that the MOO bound computed at the anchor applies along realized trajectories because the geometry does not substantially change during generation. High-drift outliers (6%) correspond to completions where the model "pivots" mid-generation (e.g., abandoning one approach for another). These cases violate the smoothness assumption and represent a known failure mode (Remark 2.9).

Pivot Regime in the Predicted-Infeasible Region. Under the audit-observer measurement (1,365 high-tier trials across 17 LLMs from two families), unconditional high-tier pass rate is 67.6% (923/1,365); the paper's headline 0/1,365 high-tier refutations imply, by exclusion, that all passes occur in the pivot regime under the audit observer's per-(observer, model) calibration. Smooth trajectories satisfy the Lipschitz contract and obey the bound (the smooth regime is small under audit-observer measurement: $\sim$4% of non-control trials); pivot trajectories violate it and admit successes. **Contact ratio.** The 4% smooth fraction is the *contact ratio* between deterministic compute and the substrate. Where the contract holds, the bound predicts to within Wilson 0.86%. The 96% pivot fraction is substrate moving through states compute cannot directly observe mid-step. Pivot signatures are the indirect read. The smooth/pivot decomposition is the visibility threshold of deterministic measurement, not the bound's operating range. The verifier-surface alignment between Claude family* (83% high-tier pass) and open-weight family (45% high-tier pass) is the active investigation flagged by the audit observer's stream-level verdict (`verifier_surface_mismatch`, Sec. 6). Pivot signatures are detectable mid-generation, specifically per-token displacement exceeding $2.5\hat{L}$ or constraint-direction drift exceeding 15°. The $2.5\hat{L}$ cutoff sits between the empirical 95th and 99th step-percentile (App. K, $p_{95}{\approx}0.14$, $p_{99}{\approx}0.25$); it was set after observing the displacement distribution, not pre-registered, so the resulting smooth/pivot fractions are conditional on this choice. Robustness checks at $2.0\hat{L}$ and $3.0\hat{L}$ shift the pivot fraction by <3pp without changing the smooth-regime refutation count. Algorithm 1 can early-stop one-shot and switch to staging on detection. Pivots manifest as detectable contract violations rather than silent failures, which is the fail-safe property under the displacement contract.

Table A16: Per-tier success decomposition (code constraint benchmark, N=480 per tier, 4 models $\times$ 2 protocols). Smooth-regime size from $1-\hat{p}_{\text{pivot}}$ where $\hat{p}_{\text{pivot}}$ averages 96% across models under the audit-observer measurement (Table A17). Pivot successes inferred by exclusion from the 0/1,365 high-tier refutation count (audit-observer run).

Tier	Trials	Pass	Smooth pass	Pivot pass
Control ($\hat{\rho}\approx0.05$)	480	76.9%	high	rare
Low ($\hat{\rho}\approx0.20$)	480	58.1%	dominant	rare
Moderate ($\hat{\rho}\approx0.40$)	480	23.1%	mixed	mixed
High ($\hat{\rho}\approx0.65$)	**480**	**1.7%**	**0/427**	**8/53 (15%)**

Wilson 95% intervals (preferred over normal approximation near 0/1): smooth-pass $0/427$ has one-sided upper bound 0.86%; pivot-pass $8/53 = 15.1\%$ has interval $[7.5\%, 27.6\%]$.

Forbidden-pivot escape-library tightening (v2 verifier). The pivot-regime decomposition above relies on the AST verifier rejecting all attempts that satisfy the no-loops/no-recursion constraints by routing through a banned library function. The first-pass verifier (`openrouter_forbidden_pivot_results_v1_lenient.json`, archived) admitted code that called `math.factorial`, `math.gcd`, `re.findall`, and `sorted(...)[-1]`, which inflated the apparent silent-refutation rate. The current verifier in `openrouter_forbidden_pivot_harness.py` adds an `ESCAPE_LIBRARIES` table per task (e.g., for "factorial": {(`math`, `factorial`), (`math`, `prod`), (`functools`, `reduce`)}) plus AST checks for comprehensions, `sorted`-indexed extrema, `divmod`, and ternary expressions. The premier-tier conflicting joint-pass rate dropped from 100% (v1, lenient) to 72% (v2, tightened); the pivot rate rose from ∼11% to 78% on the affected tasks. Both archived and current verifier outputs are shipped for audit; only the v2 numbers are referenced by the body and the certificate.

K Lipschitz Calibration

The token→norm contract (Eq. 1) assumes bounded per-token displacement L in embedding space. We calibrate L empirically across models, tasks, and decoding settings.

Table A17: Token→norm calibration ($\pm$ standard deviation across N=50 completions over 6 code tasks). $\hat{L}$: per-token displacement in MiniLM-L6-v2 embedding space. Default $\hat{L} \approx 0.048$. Calibration script: `supplementary/experiments/lipschitz_calibration.py`.

Model	$\hat{L}$
Qwen-2.5-Coder	0.048 ± 0.008
DeepSeek-Coder	0.049 ± 0.007
TinyLlama-1.1B	0.045 ± 0.008

Encoder sensitivity (relocated from body §6). $\hat{L}$ measures step magnitude, not semantic direction. It is model-stable: $\hat{L} \in [0.045, 0.049]$ across the three open-weight models in Table A17. Default $\hat{L} \approx 0.048$. Regime ordering ($\hat{\rho}$) preserves: $r_s \geq 0.94$ across encoders.

Method. For each model and task, we generate 50 completions at T=0.7 and measure $\|x_{t+1} - x_t\|$ for each token t using MiniLM-L6-v2 embeddings. We report mean $\pm$ std of the per-token displacement aggregated across completions and tasks. Calibration script: `supplementary/experiments/lipschitz_calibration.py`.

Results.

- **Model variance:** Qwen-2.5-Coder: $\hat{L} = 0.048 \pm 0.008$; DeepSeek-Coder: $\hat{L} = 0.049 \pm 0.007$; TinyLlama: $\hat{L} = 0.045 \pm 0.008$. Per-completion mean displacements are tightly clustered ($\hat{L}$ ranges across models within ∼10%).
- **Smooth/pivot decomposition:** The $4\%/96\%$ smooth-vs-pivot split under audit-observer measurement (Sec. 6, 5,472 trials across 17 LLMs) characterizes when generation behaves

as bounded-displacement vs. recomposition; per-model $\hat{L}$ above is computed across all completions. Pivot detection lives at the trajectory level, not the per-model aggregate.

Step-Size Distribution (The 'Aha!' Question). A single token like "not" can invert semantic meaning. Does this invalidate the Lipschitz bound? **No: the bound is on embeddings, not tokens.** Token space is discrete. Embedding space is continuous. We measure displacement *in embedding space*, where even semantically disruptive tokens induce bounded movement. We analyze the *distribution* of per-token displacements across 900 completions (50 per task $\times$ 6 tasks $\times$ 3 models, N=108,957 tokens). **Findings:** 95th percentile $\|x_{t+1} - x_t\| = 0.148$; 99th percentile $= 0.246$; maximum observed $= 0.447$. Semantic jumps ($> 3\sigma$) occur in 2.3% of tokens, clustered at (i) sentence boundaries, (ii) negation words, (iii) code delimiters: tokens that often *recode the constraint chart* (logical restructuring) rather than smooth interpolation. Critically, *constraint satisfaction tasks* (following formatting rules, avoiding forbidden content) involve incremental compliance, not insight pivots. 'Aha!' moments characterize *reasoning* tasks where the model discovers a solution. Constraint following is *procedural*, with smooth trajectories. The 96% pivot mass under audit-observer measurement (Sec. 6) corresponds to tasks where the model *abandons and restarts* an approach, detectable via trajectory curvature and excluded from regime prediction (Remark 2.9).

Interpretation. The stability of L across models and tasks validates the token→norm contract for regime prediction. While L varies with model size and temperature, the variation is bounded and predictable. Practitioners can use $\hat{L} \approx 0.025$ as a default. Task-specific calibration improves precision. The bound is conservative for insight-driven tasks but tight for constraint-following tasks: precisely the regime our theory addresses.

$\hat{L}$ **Perturbation Robustness.** We test routing stability under $\pm$30% perturbation of the calibrated $\hat{L}$ (analogous to $\hat{\rho}$ threshold sensitivity in Table A8). Table A18 summarizes the results.

Table A18: $\hat{L}$ perturbation robustness. Underestimating $\hat{L}$ triggers more staging (fail-safe). Overestimating risks 3% pass rate loss.

$\hat{L}$ Perturbation	Router Agree	ΔPass	Direction
-30% (conservative)	94%	$+1\%$	More staging
Baseline	100%	—	—
$+30\%$ (aggressive)	89%	-3%	More one-shot

$\hat{L}$ mis-estimation is **fail-safe in one direction**. Underestimating $\hat{L}$ (believing tokens move less than they do) makes the router conservative, staging more often and wasting tokens but not correctness. Overestimating $\hat{L}$ makes the router aggressive, risking one-shot attempts in truly infeasible regions. Practitioners should err toward lower $\hat{L}$ estimates when uncertain.

Anisotropy. Embedding spaces are anisotropic, meaning principal directions have unequal variance. Does this affect the scalar L? No. L is the operator norm (maximum singular value of the Jacobian), already worst-case over all directions. The bound is conservative. Tighter direction-dependent bounds require trajectory knowledge unavailable at routing time. Empirically, the cross-model spread of $\hat{L}$ (within $\sim$10%, Table A17) is small relative to anisotropic variation, indicating the scalar $\hat{L}$ summarizes step magnitude well enough for routing.

L Preservation Cost Analysis

Staging requires that progress on constraint C_j at stage t+1 does not regress constraint C_i satisfied at stage t. We analyze the additional cost of this preservation requirement.

Body summary (relocated from §5). Stage t+1 must not regress C_i: adds $O(\rho\tau/m)$ overhead. Empirically (App. L, 8 OpenRouter models, 240 trials per tier), test-axis stage-3 regression rises mildly with ρ (0.5% control $\to$ 1.7% high pooled). The dramatic finding is upstream: at high tier, no model satisfies the format constraint at stage 1 alone (240/240 across all 8 models). Staging cannot regress what stage 1 never satisfied.

Remark L.1 (Staging as temporal reparameterization). Diagonal cost applies to *endpoint-only* control: a single Δ achieving τ-progress on all k constraints. Staging uses $z^{(0)} \to \cdots \to z^{(S)}$ with per-stage budgets, replacing $\bigcap_i C_i$ with sequential satisfaction (POCS [Bauschke and Borwein, 1996], critique-revision [Bai et al., 2022b]). Staging does *not* assume conflicts vanish; coupling appears as preservation overhead. The diagonal cost is the price of compressing temporal structure into spatial; staging restores autoregressive degrees of freedom.

Formal Setup. At stage $t{+}1$, the model solves $\min \|\Delta\|$ subject to a progress requirement on the active constraint C_j and a non-regression requirement on every prior constraint C_i already satisfied at stages $s \le t$:

$$\langle u_j, \Delta\rangle \le -\tau/m, \qquad \langle u_i, \Delta\rangle \le 0 \;\; \forall i \in P_t,$$

where $P_t = \{\pi(s) : s \le t\}$ indexes the prior set, $|P_t| = p$. We assume uniform magnitudes $m_i = m$ for clarity; the general case scales each row by m_i without changing the structure.

Preservation Cost Bound (general k). When all preservation halfspaces are active (worst case), KKT optimality places Δ in $\mathrm{span}\{u_i : i \in P_t \cup \{j\}\}$. Let G_P be the Gram of prior unit gradients and $h \in \mathbb{R}^p$ collect the inner products $h_i = \langle u_i, u_j\rangle$. The preservation-constrained minimum-norm step satisfies

$$\|\Delta_{\text{preserve}}\|^2 = \frac{(\tau/m)^2}{1 - h^\top G_P^{-1} h}. \tag{A1}$$

The denominator is the squared component of u_j orthogonal to $\mathrm{span}\{u_i : i \in P_t\}$; it vanishes precisely when u_j enters that span, i.e., when G_P becomes singular along the direction of h.

Specialization: $k = 2$. For $p = 1$, $G_P = [1]$ and $h = [-\rho]$, so $h^\top G_P^{-1} h = \rho^2$. The minimum-norm step has magnitude

$$\|\Delta_{\text{preserve}}\| = \frac{\tau}{m} \cdot \frac{1}{\sqrt{1-\rho^2}},$$

giving overhead factor $1/\sqrt{1-\rho^2}$, bounded for $\rho < 1$. At $\rho = 0.5$, overhead is $1/\sqrt{0.75} - 1 \approx 15.5\%$ (not 33%; the $1/(1-\rho^2)$ factor is the squared-norm ratio, not the displacement ratio).

Specialization: uniform conflict, general k. For uniform pairwise conflict $\rho_{ij} = -\rho$, $G_P = (1+\rho)I_p - \rho\mathbf{1}\mathbf{1}^\top$ has $G_P\mathbf{1} = (1 - \rho(p-1))\mathbf{1}$, and $h = -\rho\mathbf{1}$. Thus

$$h^\top G_P^{-1} h = \rho^2 \cdot \frac{p}{1 - \rho(p-1)},$$

and substituting into (A1) and simplifying via $1 - \rho(p-1) - p\rho^2 = (1+\rho)(1-\rho p)$ yields

$$\|\Delta^{(p)}_{\text{preserve}}\| = \frac{\tau}{m} \cdot \sqrt{\frac{1 - \rho(p-1)}{(1+\rho)(1-\rho p)}}. \tag{A2}$$

The overhead diverges as $\rho p \to 1$, equivalently as $\hat\rho(p) \to 1$ in the conflict-degree notation $\hat\rho(p) := \rho p$. At the final stage ($p = k-1$), this is the same rank-deficiency boundary $\hat\rho(k-1) \to 1$ that governs the simultaneous Gram-spectrum bound (Theorem M.6).

Empirical Regression Rates. We instrument the 3-stage protocol to capture stage-1 (correctness-focused) and stage-3 (final) outputs separately, evaluating each against tests and format. Across 8 OpenRouter models (gemini-2.5-flash, gpt-4o-mini, claude-haiku-3.5, llama-3.1-70b, deepseek-v3, mistral-large, gpt-4o, claude-sonnet-4.5), 6 tasks, 5 trials per cell, 240 trials per tier:

- **Test-axis regression** (stage-1 passes tests $\to$ stage-3 fails tests, conditional on stage-1 success): 0.5% control, 0.6% low, 1.1% moderate, 1.7% high. Monotone-rising but modest in absolute terms. Per-model variance is large: most models exhibit 0% across all tiers; a few (claude-haiku-3.5, deepseek-v3, mistral-large) account for the pooled rise.

- **Format-axis collapse at stage 1**: stage-1 cells satisfying the format constraint drop from 239/240 (control) to 56/240 (low) to 23/240 (moderate) to *0/240* (high). This is universal: every one of the 8 models hits 0/30 at high tier. The conjunction collapse manifests at stage 1, before staging can intervene; staging cannot regress what stage 1 never satisfied.

Implication: the dominant high-ρ failure mode is *single-axis infeasibility under the harder marginal*, not cross-axis interference at stage transitions. The diagonal cost forces format-axis collapse before the staged decomposition can run.

M Proofs of Main Results

This appendix provides complete proofs of the lower bounds on feasible progress under multiple simultaneously active constraints, as stated in the main paper.

Remark M.1 (Applicability, relocated from body §3). $\rho < 1/(k-1)$ ensures $\Gamma \succ 0$; our $\rho_{\max} \approx 0.12$–0.20 satisfies for $k \leq 4$. Under convex exit-cone assumptions, linear infeasibility implies trajectory infeasibility (Theorem N.6).

Why quadratic geometry. Constraint gradients define half-spaces; their intersection is a convex polytope regardless of model nonlinearity. Curvature affects whether the displacement contract holds, not the geometry once it does. Curved paths do not escape the bound (Theorem N.6).

Classical vs. Novel. The projection geometry and Karush-Kuhn-Tucker (KKT) machinery are standard [Boyd and Vandenberghe, 2004, Horn and Johnson, 2013]. Our contribution is the *explicit conflict parameterization*: expressing $\|d^\star\|$ directly as a function of ρ_{ij} reveals the diagonal cost structure that classical treatments leave implicit. This parameterization enables the operational interpretations (staging benefit, feasibility cliff) central to the main text.

M.1 Preliminaries and Notation

Let $(\mathcal{M}, \langle\cdot,\cdot\rangle)$ be a finite-dimensional real inner product space. At $x \in \mathcal{M}$, associate k differentiable scalar objectives $L_i : \mathcal{M} \to \mathbb{R}$ with gradients $g_i = \nabla L_i(x)$ and magnitudes $m_i = \|g_i\|$. We define first-order feasible displacement $d \in \mathcal{M}$ as satisfying

$$\langle g_i, d\rangle \leq -\tau \quad \text{for all } i. \tag{F}$$

where $\tau > 0$ is a fixed local decrease requirement. This standard linearization appears throughout convex and multiobjective optimization [Fliege and Svaiter, 2000, Boyd and Vandenberghe, 2004].

Pairwise conflict is quantified via cosine similarity $c_{ij} := \langle u_i, u_j\rangle \in [-1, 1]$ where $u_i = g_i/\|g_i\|$. Following Def. 2.6, the *conflict magnitude* is $\rho_{ij} := -c_{ij} \in (0, 1]$ for conflicting constraints ($c_{ij} < 0$). **Notation:** In derivations below, c denotes cosine similarity. For conflicting constraints, $c = -\rho$ where $\rho > 0$ is the conflict magnitude used in the main text theorems. The Gram matrix $\Gamma \in \mathbb{R}^{k\times k}$ has entries $\Gamma_{ij} = \langle g_i, g_j\rangle = m_i m_j c_{ij}$.

Assumptions. We explicitly state the minimal assumptions needed for our lower bounds:

1. **Locality:** First-order approximations hold for $\|d\| \leq \delta$, as in standard analyses of local descent.
2. **Smoothness:** $|\langle g_i, d\rangle| \leq m_i\|d\|$ uniformly in the local neighborhood. This matches classical Lipschitz gradient assumptions [Boyd and Vandenberghe, 2004, Nesterov, 2018].
3. **Non-degeneracy:** At least one $g_i \neq 0$.

Operational contribution. While the fundamental objects above are classical, our main paper's *diagonal cost interpretation* arises by expressing lower bounds on $\|d\|$ *directly as a function of conflict ρ_{ij} and magnitudes m_i*. This quantifies how constraint coupling amplifies required progress.

Lemma M.2 (First-Order Lower Bound). *For any differentiable function $L : \mathcal{M} \to \mathbb{R}$ and displacement d satisfying $\langle\nabla L(x), d\rangle \leq -\tau$, we have $\|d\| \geq \tau/\|\nabla L(x)\|$.*

Proof. The descent condition $\langle \nabla L(x), d\rangle \le -\tau$ implies $|\langle \nabla L(x), d\rangle| \ge \tau$. Applying the Cauchy–Schwarz inequality yields $|\langle \nabla L(x), d\rangle| \le \|\nabla L(x)\|\|d\|$. Combining these two bounds gives the stated result $\|d\| \ge \tau/\|\nabla L(x)\|$. □

Path Integration vs. Displacement Feasibility. Autoregressive decoding traverses a token path. Our proofs analyze *displacement feasibility*: existence of a chord Δ from x_0 to a satisfying endpoint within $B_\delta \cap E(x_0)$. The diagonal cost bound is a *necessary condition* on $\|\Delta\|$; search dynamics are addressed in Sec. M.14.

M.2 Convex Feasibility and Projection Geometry

We review standard results to establish notation consistency. The feasible set $\mathcal{C}$ of first-order satisfying displacements is

$$\mathcal{C} = \{d \in \mathcal{M} : \langle g_i, d\rangle \le -\tau \;\; \forall i\},$$

an intersection of closed half-spaces. As shown in Boyd and Vandenberghe [2004, Sec. 2.2], $\mathcal{C}$ is nonempty iff feasibility holds.

Lemma M.3 (Projection characterization; classical)**.** *If $\mathcal{C}$ is nonempty, the minimum-norm feasible displacement*

$$d^\star = \arg\min_{d\in\mathcal{C}} \|d\|$$

exists and is unique, and is equal to the projection of the origin onto $\mathcal{C}$ [Boyd and Vandenberghe, 2004, Thm. 2.1].

This standard observation reduces the lower-bound problem to characterizing the norm of the projected solution.

Lemma M.4 (Minimum-Norm Halfspace Intersection)**.** *Let $\mathcal{H}_1 = \{d : \langle u, d\rangle \le -\alpha_1\}$ and $\mathcal{H}_2 = \{d : \langle v, d\rangle \le -\alpha_2\}$ where $u, v \in \mathcal{M}$ are unit vectors with cosine $c := \langle u, v\rangle \in (-1, 1)$. The minimum-norm point in $\mathcal{H}_1 \cap \mathcal{H}_2$ is:*

$$d^\star = \frac{-\alpha_1 + \alpha_2 c}{1 - c^2} u + \frac{-\alpha_2 + \alpha_1 c}{1 - c^2} v.$$

For conflicting constraints ($c < 0$), substituting $c = -\rho$ where $\rho > 0$ is the conflict magnitude yields the main-text formula.

Proof. The minimum-norm feasibility problem is a convex QP [Boyd and Vandenberghe, 2004, Chap. 4]. The Lagrangian is:

$$\mathcal{L}(d, \lambda_1, \lambda_2) = \tfrac{1}{2}\|d\|^2 + \lambda_1(\langle u, d\rangle + \alpha_1) + \lambda_2(\langle v, d\rangle + \alpha_2).$$

Setting $\nabla_d \mathcal{L} = 0$: $d = -\lambda_1 u - \lambda_2 v$.

By complementary slackness [Boyd and Vandenberghe, 2004, Sec. 5.5.2], both constraints are active at optimum:

$$-\lambda_1 - \lambda_2 c = -\alpha_1$$
$$-\lambda_1 c - \lambda_2 = -\alpha_2$$

The system has determinant $1 - c^2 > 0$ for $|c| < 1$. Solving via Cramer's rule yields the stated form. □

M.3 Two-Constraint Lower Bound (Theorem 3.3)

The following theorem corresponds to Theorem 3.3 in the main text, now presented with its complete derivation. Recall: c denotes cosine similarity, and for conflicting constraints, $c = -\rho$ where $\rho > 0$ is the conflict magnitude.

Theorem M.5 (Two-constraint lower bound; explicit conflict instantiation)**.** *Let $g_1, g_2 \in \mathcal{M}$ be nonzero gradients with magnitudes m_1, m_2 and conflict magnitude $\rho > 0$ (cosine $c = -\rho$). Assume feasibility holds. Then every d satisfying* (F) *obeys*

$$\|d\| \;\ge\; \sqrt{\frac{\alpha_1^2 + \alpha_2^2 + 2\rho\,\alpha_1\alpha_2}{1 - \rho^2}}, \qquad \alpha_i := \tau/m_i.$$

Classical structure. The derivation utilizes the standard identity $\|d\|^2 = \tau^2 \mathbf{1}^\top \Gamma^{-1} \mathbf{1}$ for active constraints [Boyd and Vandenberghe, 2004, cf. pp. 231–233], combined with basic properties of Gram matrices [Horn and Johnson, 2013].

Proof. Let $u_i = g_i/m_i$ be unit gradient directions with cosine $c = \langle u_1, u_2 \rangle = -\rho$. Under the conflict hypothesis $\rho > 0$, both constraints are active at the minimum-norm solution: if only one were active, the unconstrained projection onto that single halfspace would already violate the other (since their inward normals have negative inner product). See Boyd and Vandenberghe 2004, Sec. 3.2 for the KKT setup. We solve the KKT system. By Lemma M.4 with $\alpha_i = \tau/m_i$:

$$d^\star = \gamma_1 u_1 + \gamma_2 u_2, \quad \gamma_i = \frac{-\alpha_i + \alpha_j c}{1 - c^2}.$$

The Gram matrix of unit gradients is $G = \begin{pmatrix} 1 & c \\ c & 1 \end{pmatrix}$ with $G^{-1} = \frac{1}{1-c^2} \begin{pmatrix} 1 & -c \\ -c & 1 \end{pmatrix}$.

Computing $\|d^\star\|^2 = \gamma_1^2 + \gamma_2^2 + 2\gamma_1\gamma_2 c$ and simplifying:

$$\|d^\star\|^2 = \frac{\alpha_1^2 + \alpha_2^2 - 2c\alpha_1\alpha_2}{1 - c^2}.$$

For the uniform case $\alpha_1 = \alpha_2 = \tau/m$, substituting $c = -\rho$:

$$\|d^\star\|^2 = \frac{2(\tau/m)^2(1+\rho)}{1-\rho^2} = \frac{2\tau^2}{m^2(1-\rho)}.$$

Taking square roots yields the main-text formula:

$$\|d^\star\| = \frac{\tau}{m}\sqrt{\frac{2}{1-\rho}}.$$

□

Operational interpretation (our contribution). While the above steps are classical, expressing the denominator directly in terms of ρ and m_i makes the *amplification of feasible progress cost under conflict* explicit, establishing the diagonal cost phenomenon central to the main paper.

M.4 k-Constraint Lower Bound (Theorem 3.6)

Theorem M.6 (k-constraint lower bound; Gram-spectrum formulation)**.** *Let $G \in \mathbb{R}^{k \times \dim(\mathcal{M})}$ collect unit gradients row-wise, and $\Gamma = GG^\top$ be the Gram matrix. Assume Γ is positive definite. Then every d satisfying* (F) *obeys*

$$\|d\| \;\geq\; \frac{\tau}{m}\sqrt{\mathbf{1}^\top \Gamma^{-1} \mathbf{1}} \;\geq\; \frac{\tau}{m}\sqrt{\frac{k}{1-\rho(k-1)}}, \tag{A3}$$

where the second inequality assumes uniform pairwise conflict $\rho_{ij} \leq -\rho$ for all $i \neq j$.

Proof. The projection argument follows Lemma M.3, yielding the minimum-norm feasibility problem:

$$\min_d \ \tfrac{1}{2}\|d\|^2 \quad \text{s.t.} \quad \langle u_i, d \rangle \leq -\alpha \quad \forall i,$$

where $\alpha = \tau/m$ and u_i are unit gradient directions.

At optimality, by KKT conditions, $d^\star = -\sum_i \lambda_i u_i$ where $\lambda \geq 0$. For symmetric constraints with uniform α, symmetry implies $\lambda_i = t$ for all i. Then $Gd^\star = -t\Gamma\mathbf{1} = -\alpha\mathbf{1}$, so $d^\star = -\alpha G^\dagger \mathbf{1} = -\alpha G^\top (GG^\top)^{-1}\mathbf{1}$ [Horn and Johnson, 2013, Chap. 6].

Computing the norm:

$$\|d^\star\|^2 = \alpha^2 \mathbf{1}^\top \Gamma^{-1}\Gamma\Gamma^{-1}\mathbf{1} = \alpha^2 \mathbf{1}^\top \Gamma^{-1} \mathbf{1}.$$

For the uniform conflict bound, when $\langle u_i, u_j \rangle = -\rho$ for all $i \neq j$:

$$\Gamma = (1+\rho)I - \rho\mathbf{1}\mathbf{1}^\top.$$

By the Sherman-Morrison formula [Horn and Johnson, 2013]:

$$\Gamma^{-1} = \frac{1}{1+\rho}\left(I + \frac{\rho}{1-\rho(k-1)}\mathbf{1}\mathbf{1}^\top\right).$$

Thus $\mathbf{1}^\top\Gamma^{-1}\mathbf{1} = \frac{k}{1-\rho(k-1)}$, yielding the stated bound. **Symbolic verification:** SymPy derivation confirms this formula exactly for $k \in \{2,3,4,5\}$ with phase transition at $\rho = 1/(k-1)$. Code: `supplementary/bridges/gram_matrix_verification.py`. □

Operational contribution. While (A3) is structurally classical, our main paper uses this expression to quantify *how conflict structure (via the Gram spectrum)* governs *observable failure thresholds* in multi-constraint satisfaction.

M.5 Staging Benefit Analysis

We now prove that staged satisfaction reduces required step magnitude when constraints are resolved sequentially.

Why staging escapes implicit-k. One-shot generation must respect all k constraint gradients simultaneously, holding the full Gram matrix Γ in budget. When implicit constraints (grammar, coherence) inflate k, the diagonal cost bound becomes restrictive. Staging escapes this. Each step resolves one constraint, requiring only one gradient at a time. The model never needs to compute or budget for the global geometry. It iteratively constructs a solution where step $t+1$ takes x_t as a fixed anchor. This is why staging circumvents the "implicit k is unknowable" objection. The bound applies to simultaneous satisfaction, not sequential.

Proposition M.7 (Staging reduces diagonal cost)**.** *Let k constraints have uniform pairwise conflict $\rho_{ij} = -\rho$, and assume the staging feasibility condition $\hat{\rho}(k-1) := \rho(k-1) < 1$ (equivalently, the prior-set Gram G_P remains positive definite at every stage). Then sequential satisfaction with min-norm preservation has stage-p step magnitude*

$$\delta^{(p)}_{staged} \;=\; \frac{\tau}{m}\sqrt{\frac{1-\rho(p-1)}{(1+\rho)(1-\rho p)}}, \qquad p = 0, 1, \ldots, k-1,$$

(see (A2)*; $p = 0$ gives the unconstrained τ/m). Simultaneous satisfaction requires a single step with*

$$\delta_{sim} \;\geq\; \frac{\tau}{m}\sqrt{\frac{k}{1-\rho(k-1)}} \qquad \textit{(Theorem M.6).}$$

Both blow up at the rank-deficiency boundary $\hat{\rho}(k-1) \to 1$; staging does not *relax this boundary, but it changes the prefactor.*

Proof. Single-constraint min-norm progress is τ/m by Cauchy-Schwarz (Lemma M.2). Adding p active non-regression halfspaces yields the constrained min-norm problem of Sec. L; substituting the uniform-conflict Gram into (A1) gives (A2). Feasibility of the stage-p subproblem requires the orthogonal complement of $\mathrm{span}\{u_i : i \in P_t\}$ to contain a descent direction for u_j, equivalently $h^\top G_P^{-1} h < 1$; under uniform conflict this reduces to $\rho p < 1$. Taking the worst stage $p = k-1$ gives $\hat{\rho}(k-1) < 1$. The simultaneous bound is Theorem M.6. □

Corollary M.8 (Per-step ratio and total displacement)**.** *At the worst (final) stage $p = k-1$, the per-step ratio is*

$$\frac{\delta_{sim}}{\delta^{(k-1)}_{staged}} \;=\; \sqrt{\frac{k(1+\rho)}{1-\rho(k-2)}},$$

finite even as $\hat{\rho}(k-1) \to 1$ (both diverge at the same rate $1/\sqrt{1-\rho(k-1)}$). Summing total displacement across the k stages, $\Delta^{tot}_{staged} = \sum_{p=0}^{k-1} \delta^{(p)}_{staged}$ is dominated by the last term, so $\Delta^{tot}_{staged} \asymp k\tau/m$ for ρ bounded away from the boundary, versus $\delta_{sim} \asymp (\tau/m)\sqrt{k/(1-\rho(k-1))}$ in one shot. Staging is preferred when $\sqrt{k/(1-\rho(k-1))} \gtrsim k$, i.e., when $\hat{\rho}(k-1) \gtrsim 1 - 1/k$.

Remark M.9 (Universal feasibility limit). For uniform pairwise conflict, both simultaneous and staged satisfaction become infeasible at the same rank-deficiency boundary $\hat{\rho}(k-1) = 1$. This is structural: at that boundary the k unit gradients become linearly dependent and the orthogonal complement of any $k-1$-subset that contains a descent direction for the remaining one collapses. No memoryless policy at fixed $(k, \tau/m)$ that respects the linearization can escape this boundary; only constraint decomposition (reducing k) or magnitude rescaling (changing τ/m) does. This motivates the Algorithm 1 guard `if` $\hat{\rho}(k-1) \geq 1$`:   return DECOMPOSE`: routing past the cliff is provably futile, not merely costly.

Connection to Constitutional AI. This proposition formalizes why critique-revision loops (Constitutional AI's core mechanism) succeed by targeting one principle per revision, avoiding the diagonal cost amplification that would arise from simultaneous multi-principle optimization.

M.6 High-ρ Bounds and Degeneracy

When $\rho \geq 1/(k-1)$, the Gram matrix Γ becomes singular or indefinite. We characterize the resulting behavior.

Proposition M.10 (Gram matrix spectrum)**.** *For k constraints with uniform pairwise conflict $\rho_{ij} = -\rho$, the Gram matrix $\Gamma = (1+\rho)I - \rho\mathbf{1}\mathbf{1}^\top$ has eigenvalues:*

- $\lambda_1 = 1 - \rho(k-1)$ *with eigenvector* $\mathbf{1}$
- $\lambda_{2,\ldots,k} = 1 + \rho$ *with multiplicity* $k-1$

Γ *is positive definite iff* $\rho < 1/(k-1)$.

Proof. Direct computation. $\Gamma\mathbf{1} = (1+\rho)\mathbf{1} - k\rho\mathbf{1} = (1-\rho(k-1))\mathbf{1}$. For $v \perp \mathbf{1}$: $\Gamma v = (1+\rho)v$. Positive definiteness requires all eigenvalues positive: $1 - \rho(k-1) > 0 \Leftrightarrow \rho < 1/(k-1)$. □

At $\rho = 1/(k-1)$, the constraint gradients become coplanar (linearly dependent), and the feasible region $\mathcal{C}$ degenerates, analogous to Slater's condition failure in convex optimization (no strictly feasible interior point). For $\rho > 1/(k-1)$, the gradients point "more than orthogonally" apart, creating an infeasible configuration where no direction simultaneously decreases all objectives.

Fragmentation regime. Our IF-DSL experiments (App. R) empirically confirm this analysis: at $\rho = 1.0$ (maximally conflicting constraints like `one_bottleneck + pathlen_eq_5`), pass rates collapse to 0% regardless of budget or protocol, matching the geometric prediction.

M.7 Tightness of Bounds

Proposition M.11 (Tightness)**.** *The bounds in Theorems M.5 and M.6 are tight: there exist constraint configurations achieving equality.*

Proof. The minimum-norm solution $d^\star$ achieving the bound exists by construction. The bound is achieved when:

1. All constraints are active at $d^\star$ (no slack)
2. The constraint normals span the subspace containing $d^\star$

For $k = 2$ with $\rho \in (-1, 1)$, both conditions hold generically. For general k, tightness holds when the Gram matrix is positive definite and the problem is strictly feasible [Boyd and Vandenberghe, 2004, Thm. 5.2.1].

As Table A11 demonstrates, synthetic optimization matches analytical bounds to relative error $< 10^{-8}$ across all tested configurations. □

Necessity of Conflict Structure (Information-Theoretic). The parameter ρ enters necessarily. Setting $\rho = 0$ (orthogonal constraints) collapses the bound to $\|d^\star\| = \tau\sqrt{k}/m$, the axis-aligned case where no amplification occurs. The $1/(1-\rho)$ factor captures exactly the geometric cost of non-orthogonality, an information-theoretic lower bound, not a modeling choice.

Robustness Under Mild Curvature. The first-order analysis assumes locally linear constraint surfaces. Under bounded curvature $\|\nabla^2 L_i\| \leq \kappa$, the projection-based lower bound persists up to $O(\kappa\|d\|^2)$ corrections. Specifically, for $\|d\| \ll 1/\kappa$, the diagonal cost regime is not an artifact of strict linearity but reflects genuine geometric structure that curvature perturbs without eliminating.

M.8 Connection to Pareto Optimality

We establish the relationship between our lower bounds and classical Pareto theory [Ehrgott, 2005].

Definition M.12 (Pareto efficiency)**.** A point $x \in \mathcal{M}$ is *Pareto efficient* for objectives $\{L_i\}_{i=1}^k$ if there exists no x' with $L_i(x') \leq L_i(x)$ for all i and strict inequality for some i.

Proposition M.13 (Diagonal cost at Pareto points)**.** *At a Pareto efficient point $x^\star$, the minimum-norm direction achieving simultaneous first-order decrease on all objectives has norm*

$$\|d^\star\| = \tau\sqrt{\mathbf{1}^\top \Gamma^{-1}\mathbf{1}},$$

where Γ is the Gram matrix of gradients at $x^\star$. The Pareto front curvature is governed by $\rho_{\max} = \max_{i\neq j} \rho_{ij}$.

Proof. At Pareto efficiency, all constraints are active: any slack would permit Pareto improvement. Thus the minimum-norm solution lies at the intersection of all constraint hyperplanes, giving $\|d^\star\|^2 = \tau^2\mathbf{1}^\top\Gamma^{-1}\mathbf{1}$ by the derivation in Theorem M.6.

The Pareto front curvature relates to $\rho_{\max}$ because high conflict between gradients implies sharp trade-offs, since moving toward one objective moves sharply away from another, creating a highly curved front [Deb et al., 2002]. □

Corollary M.14 (Pareto navigation cost)**.** *Moving along the Pareto front by ϵ in objective i while maintaining Pareto efficiency requires displacement magnitude $\Omega(\epsilon/\sqrt{1-\rho_{\max}})$ when $\rho_{\max}$ is close to the critical threshold.*

Proof. Pareto navigation requires maintaining first-order decrease on all objectives except i. This is a $(k-1)$-constraint problem with the same conflict structure. By Theorem M.6, the minimum displacement scales as $\sqrt{(k-1)/(1-\rho_{\max}(k-2))} = \Omega(1/\sqrt{1-\rho_{\max}})$ near criticality. □

M.9 Heterogeneous Magnitudes: Complete Treatment

We extend the uniform-magnitude results to the general case where $m_i = \|g_i\|$ may differ across constraints.

Theorem M.15 (Heterogeneous diagonal cost)**.** *For k constraints with gradient magnitudes $\{m_i\}_{i=1}^k$ and pairwise conflicts $\{\rho_{ij}\}_{i<j}$, define the normalized Gram matrix $\tilde{\Gamma}$ with entries $\tilde{\Gamma}_{ij} = \rho_{ij}$ for $i \neq j$ and $\tilde{\Gamma}_{ii} = 1$. Let $M = \mathrm{diag}(m_1, \ldots, m_k)$. Then:*

$$\|d^\star\|^2 = \tau^2\mathbf{1}^\top(M\tilde{\Gamma}M)^{-1}\mathbf{1} = \tau^2\mathbf{1}^\top M^{-1}\tilde{\Gamma}^{-1}M^{-1}\mathbf{1}.$$

Proof. The Gram matrix of unnormalized gradients is $\Gamma = M\tilde{\Gamma}M$ where $\tilde{\Gamma}$ contains the correlation structure. The minimum-norm solution satisfies $\|d^\star\|^2 = \tau^2\mathbf{1}^\top\Gamma^{-1}\mathbf{1}$. Substituting and using $(ABC)^{-1} = C^{-1}B^{-1}A^{-1}$ yields the result. □

Corollary M.16 (Magnitude-conflict interaction)**.** *When constraints have heterogeneous magnitudes, the effective diagonal cost depends on both conflict structure and magnitude ratios. Specifically, for $k = 2$:*

$$\|d^\star\| = \tau\sqrt{\frac{1/m_1^2 + 1/m_2^2 + 2\rho/(m_1 m_2)}{1-\rho^2}}.$$

Large-magnitude constraints (high m_i) contribute less to the diagonal cost per unit of required decrease.

Proof. For $k = 2$, $M^{-1} = \mathrm{diag}(1/m_1, 1/m_2)$. Under the conflict convention $c = \langle u_1, u_2 \rangle = -\rho$ (so the correlation matrix has off-diagonal $-\rho$ for $\rho > 0$), $\tilde{\Gamma}^{-1} = \frac{1}{1-\rho^2}\begin{pmatrix} 1 & \rho \\ \rho & 1 \end{pmatrix}$. Computing $\mathbf{1}^\top M^{-1}\tilde{\Gamma}^{-1}M^{-1}\mathbf{1}$ and simplifying yields the stated formula. □

M.10 Iterative Satisfaction: Convergence Analysis

We analyze convergence rates for iterative methods that approximate staged satisfaction. The iterative protocol defined in Section J.14 is a behavioral instantiation of the Kaczmarz method [Kaczmarz, 1937], also known in the optimization literature as the Method of Cyclic Projections [Gubin et al., 1967]. Theorem J.15 inherits the classical linear convergence rates of these methods, adapted to the local linearized geometry of the embedding manifold.

Definition M.17 (Projected gradient iteration)**.** Given current point x_t and constraint i_t (selected cyclically or by rule), the projected gradient step is:

$$x_{t+1} = x_t - \eta_t \frac{\langle g_{i_t}, x_t - x^\star_{i_t} \rangle}{\|g_{i_t}\|^2} g_{i_t},$$

where $x^\star_{i_t}$ is the projection onto constraint i_t's satisfying halfspace.

Theorem M.18 (Cyclic projection convergence)**.** *For k constraints with pairwise conflicts $\rho_{ij} \leq \rho_{\max} < 1/(k-1)$ (so the unit gradients are linearly independent by Proposition M.10), cyclic projected gradient iteration converges linearly:*

$$\|x_T - x^\star\| \leq \left(1 - \frac{1-\rho_{\max}}{k}\right)^{T/k} \|x_0 - x^\star\|.$$

The convergence rate degrades as $\rho_{\max} \to 1$.

Proof sketch. Each projection onto constraint i's halfspace reduces squared distance to the feasible region by factor $(1 - c_i)$ where c_i depends on the angle between g_i and the current residual. For non-degenerate configurations with $\rho_{\max} < 1/(k-1)$ (Proposition M.10), the constraints are linearly independent, ensuring $c_i \geq (1 - \rho_{\max})/k$ on average over a full cycle [cf. Bauschke and Borwein, 1996, Thm. 4.1]. The product of k such contractions over one cycle yields the stated bound. □

Corollary M.19 (Iteration complexity)**.** *For ϵ-feasibility, iteration count scales as $T = O\big(k \cdot (1 - \rho_{\max})^{-1} \cdot \log(1/\epsilon)\big)$, consistent with the $1/(1-\rho)$ factor in the diagonal cost bound.*

Proof. The per-cycle contraction rate from Bauschke and Borwein [1996, Thm. 4.1] for cyclic projections onto k linearly independent halfspaces with $\rho_{\max} < 1/(k-1)$ is $1 - (1 - \rho_{\max})$ per *cycle* (not per individual projection). After C cycles ($T = kC$ projections), $\|x_T - x^\star\| \leq (1 - (1 - \rho_{\max}))^C \|x_0 - x^\star\| = \rho_{\max}^C \|x_0 - x^\star\|$. Setting this $\leq \epsilon$ and solving $C \cdot \log(1/\rho_{\max}) \geq \log(1/\epsilon)$ gives $C = O((1 - \rho_{\max})^{-1} \log(1/\epsilon))$ (using $\log(1/\rho_{\max}) \geq 1 - \rho_{\max}$ for $\rho_{\max} \in (0, 1)$), and $T = kC = O(k(1 - \rho_{\max})^{-1} \log(1/\epsilon))$ projections in total. The weaker per-projection bound $(1 - (1 - \rho_{\max})/k)^{T/k}$ in Theorem M.18 is a conservative restatement of the same per-cycle rate; the tighter per-cycle form is what produces the iteration complexity above. □

M.11 Perturbation Analysis and Robustness

We establish stability of the diagonal cost under perturbations to the constraint gradients.

Theorem M.20 (Perturbation bound)**.** *Let $\{g_i\}$ be the original gradients with Gram matrix Γ, and let $\{\tilde{g}_i\}$ be perturbed gradients with $\|g_i - \tilde{g}_i\| \leq \epsilon m_i$. Let $\tilde{\Gamma}$ be the perturbed Gram matrix. Then:*

$$\left|\sqrt{\mathbf{1}^\top \Gamma^{-1} \mathbf{1}} - \sqrt{\mathbf{1}^\top \tilde{\Gamma}^{-1} \mathbf{1}}\right| \leq O\left(\frac{k\epsilon}{\lambda_{\min}(\Gamma)}\right) \sqrt{\mathbf{1}^\top \Gamma^{-1} \mathbf{1}},$$

where $\lambda_{\min}(\Gamma) = 1 - \rho_{\max}(k-1)$ for uniform conflict.

Proof. By standard matrix perturbation theory [Horn and Johnson, 2013, Thm. 2.8], for symmetric positive definite Γ and perturbation $\Delta\Gamma$ with $\|\Delta\Gamma\| \le \delta$:

$$\|\Gamma^{-1} - (\Gamma + \Delta\Gamma)^{-1}\| \le \frac{\delta}{\lambda_{\min}(\Gamma)(\lambda_{\min}(\Gamma) - \delta)}.$$

The perturbation $\|\Delta\Gamma\| = O(k\epsilon \max_i m_i^2)$ since each entry of Γ changes by at most $O(\epsilon m_i m_j)$. Applying to the quadratic form $\mathbf{1}^\top \Gamma^{-1} \mathbf{1}$ and taking square roots yields the bound. □

Corollary M.21 (Robustness near criticality). *As $\rho \to 1/(k-1)$, $\lambda_{\min}(\Gamma) \to 0$ and the diagonal cost becomes increasingly sensitive to perturbations, explaining the empirical pattern in which high-conflict configurations exhibit unstable behavior (small changes in constraint specification can dramatically alter feasibility).*

Proof. From Theorem M.20, the relative perturbation in diagonal cost is $O(k\epsilon/\lambda_{\min}(\Gamma))$. By Proposition M.10, $\lambda_{\min}(\Gamma) = 1 - \rho(k-1)$ for uniform conflict. As $\rho \to 1/(k-1)$, $\lambda_{\min} \to 0$, causing the perturbation bound to diverge. This formalizes the instability observed in high-conflict regimes. □

M.12 Algorithmic Implications

Our bounds have direct implications for algorithm design in multi-constraint optimization.

Proposition M.22 (Optimal constraint ordering for staging). *For staged satisfaction of k constraints, the optimal ordering minimizes total path length. Given conflict matrix P with $P_{ij} = \rho_{ij}$, the optimal ordering π satisfies:*

$$\pi^\star = \arg\min_{\pi} \sum_{t=1}^{k-1} \sqrt{1 + 2\sum_{s<t} \rho_{\pi(s)\pi(t)}}.$$

For $k = 2$: satisfy the higher-magnitude constraint first.

Proof. At each stage t, we satisfy constraint $\pi(t)$ while preserving $\{\pi(1), \ldots, \pi(t-1)\}$. The preservation requirement adds effective conflict from previously satisfied constraints. The minimum-norm step at stage t has magnitude determined by the effective Gram matrix of $\{g_{\pi(1)}, \ldots, g_{\pi(t)}\}$. Summing over stages and minimizing over orderings yields the optimization problem.

For $k = 2$: satisfying the larger-magnitude constraint first means subsequent preservation is easier (moving in the high-m direction requires less displacement per unit of τ). □

Remark M.23 (Comparison to gradient conflict methods). Our ordering criterion differs from PCGrad [Yu et al., 2020] and CAGrad [Liu et al., 2021], which project conflicting gradients during *training* (weight updates). Our analysis operates at *inference time* on a frozen model, controlling generation trajectory rather than training dynamics. Both address the same conflict geometry ($\rho_{ij} < 0$) at different stages, with PCGrad/CAGrad reducing conflict during parameter optimization while we detect and route around it during output optimization.

M.13 Extension to Inequality Constraints

The main results extend to mixed equality/inequality constraint settings.

Proposition M.24 (Active set characterization). *Consider k inequality constraints $\langle g_i, d\rangle \le -\tau_i$ where some may be inactive at the optimum. Let $\mathcal{A} \subseteq \{1, \ldots, k\}$ denote the active set. Then:*

$$\|d^\star\|^2 = \boldsymbol{\tau}_{\mathcal{A}}^\top \Gamma_{\mathcal{A}}^{-1} \boldsymbol{\tau}_{\mathcal{A}},$$

where $\Gamma_{\mathcal{A}}$ is the Gram matrix restricted to active constraints and $\boldsymbol{\tau}_{\mathcal{A}}$ is the corresponding vector of thresholds.

Proof. By KKT conditions, inactive constraints have zero multipliers and don't affect the optimal solution; the active constraints in turn form an equality system, reducing to the previous analysis. □

Corollary M.25 (Diagonal cost is determined by hardest subset)**.** *The diagonal cost is determined by the maximally conflicting active subset. Adding easy (orthogonal) constraints doesn't increase the bound, but adding conflicting constraints may activate new constraints and increase the cost.*

Proof. By Proposition M.24, only active constraints contribute to $\|d^\star\|$. If a new constraint j is orthogonal to all active constraints ($\rho_{ij} = 0$ for $i \in \mathcal{A}$), the augmented Gram matrix is block-diagonal and $\|d^\star\|$ depends only on $\Gamma_{\mathcal{A}}$. If j conflicts with active constraints, it may become active, enlarging $\mathcal{A}$ and potentially increasing the diagonal cost via the $\mathbf{1}^\top \Gamma^{-1} \mathbf{1}$ term. □

M.14 Global Extension

The bounds established above are local, holding within neighborhoods where first-order approximations apply; we now show they integrate to a global constraint.

Theorem M.26 (Global Diagonal Cost)**.** *Let $\gamma : [0,1] \to \mathcal{M}$ be any trajectory achieving τ-progress on all k constraints, i.e., $r_i(\gamma(1)) \le r_i(\gamma(0)) - \tau$ for all i. Under bounded curvature ($\|\nabla^2 r_i\| \le \kappa$ everywhere), the arc length satisfies:*

$$\int_0^1 \|\dot{\gamma}(t)\|\, dt \;\ge\; \frac{\tau}{m}\sqrt{\frac{k}{1-\bar{\rho}(k-1)}} - O(\kappa\tau),$$

where $\bar{\rho} := \frac{1}{\tau}\int_0^\tau \rho(\gamma(\tau'))\, d\tau'$ is the progress-weighted *path-averaged conflict (the average conflict per unit of progress made) and $m = \min_i \|\nabla r_i\|$. Progress-weighting is the operationally meaningful average: arc length is the cost the algorithm spends to buy progress, so the relevant mean of ρ is taken against the progress measure $d\tau$, not against arc length $\|\dot{\gamma}\|\, dt$.*

Proof. Partition $[0,1]$ into N segments $[t_j, t_{j+1}]$ with $\|\gamma(t_{j+1}) - \gamma(t_j)\| = \epsilon := L/N$ where L is total arc length. On each segment:

Step 1 (Local bound applies): By Lemma N.4, the residual satisfies $r_i(\gamma(t_{j+1})) = r_i(\gamma(t_j)) + \langle \nabla r_i(\gamma(t_j)), \Delta_j\rangle + O(\kappa\epsilon^2)$ where $\Delta_j = \gamma(t_{j+1}) - \gamma(t_j)$. For τ_j-progress on segment j, the local bound (Theorem 3.6) requires:

$$\|\Delta_j\| \ge \frac{\tau_j}{m_j}\sqrt{\frac{k}{1-\rho_j(k-1)}} - O(\kappa\epsilon^2/\tau_j),$$

where $\rho_j = \rho(\gamma(t_j))$ and $m_j = \min_i \|\nabla r_i(\gamma(t_j))\|$.

Step 2 (Sum over segments): Total progress $\tau = \sum_j \tau_j$. Summing the local bounds:

$$L = \sum_j \|\Delta_j\| \;\ge\; \sum_j \frac{\tau_j}{m_j}\sqrt{\frac{k}{1-\rho_j(k-1)}} \;-\; R_N, \qquad R_N := \sum_j O(\kappa\epsilon^2/\tau_j).$$

With $\epsilon = L/N$ and a uniform refinement giving $\tau_j \sim \tau/N$, $R_N = O(\kappa L^2/\tau)\cdot O(1/N) \to 0$ as $N \to \infty$, so the additive Riemann correction R_N vanishes in the limit and *does not* appear in the final bound. The persistent, non-vanishing curvature contribution is reintroduced as a single $O(\kappa\tau)$ term in Step 3 below: it arises from the per-segment Taylor remainders summed along the path, $\sum_j \kappa\epsilon^2/\tau_j \to \kappa L^2/\tau = O(\kappa\tau)$ once $L = O(\tau/m)$ is substituted back.

Step 3 (Limit, integration against the progress measure): Reparameterize by progress: let $\tau'(t) := \frac{1}{k}\sum_i \left[r_i(\gamma(0)) - r_i(\gamma(t))\right]_+$ be the cumulative mean progress along γ, so τ' runs from 0 to τ and $\tau_j = \Delta\tau'_j$ on each segment. The Riemann sum $\sum_j (\tau_j/m_j)\, f(\rho_j)$ converges, as $N \to \infty$, to a Stieltjes integral against the *progress measure* $d\tau'$:

$$L \;\ge\; \int_0^\tau \frac{1}{m(\gamma(\tau'))}\, f(\rho(\gamma(\tau')))\, d\tau', \qquad f(\rho) := \sqrt{\tfrac{k}{1-\rho(k-1)}}.$$

Convexity of f. Set $u(\rho) := 1 - \rho(k-1) \in (0,1]$ for $\rho \in [0, 1/(k-1))$. Then $f = \sqrt{k}\, u^{-1/2}$, and a direct calculation gives $f''(\rho) = \frac{3\sqrt{k}}{4}(k-1)^2\, u^{-5/2} > 0$, so f is strictly convex on the entire feasible interval $[0, 1/(k-1))$.

Jensen against the progress measure. Since $d\tau'/\tau$ is a probability measure on $[0,\tau]$ and f is convex, Jensen's inequality yields

$$\frac{1}{\tau}\int_0^{\tau} f(\rho(\gamma(\tau')))\,d\tau' \;\ge\; f\!\left(\frac{1}{\tau}\int_0^{\tau}\rho(\gamma(\tau'))\,d\tau'\right) \;=\; f(\bar\rho),$$

where $\bar\rho$ is exactly the progress-weighted average defined in the theorem statement. (An arc-length-weighted definition of $\bar\rho$ would mismatch the integration measure and invalidate this step, since arc-length and progress weighting agree only when $\|\dot\gamma\|$ is constant on level sets of progress; matching the average to the measure is the substantive correction here.) Bounding $1/m(\gamma(\tau')) \ge 1/m$ with $m := \max_{\tau'\in[0,\tau]} \min_i \|\nabla r_i(\gamma(\tau'))\|$ (the worst-case minimum-gradient norm along the path, consistent with the conservative normaliser $m = \min_i \|\nabla r_i\|$ used elsewhere) and combining,

$$L \;\ge\; \frac{\tau}{m}\sqrt{\frac{k}{1-\bar\rho(k-1)}} \;-\; O(\kappa\tau),$$

where the $O(\kappa\tau)$ residual is the persistent curvature term identified in Step 2. The constant in front of $\sqrt{k/(1-\bar\rho(k-1))}$ is unchanged from the original statement; only the definition of $\bar\rho$ (now progress-weighted) has been corrected. ☐

Corollary M.27 (Curvature cannot defeat the bound)**.** *The global bound has the same $\sqrt{k/(1-\rho(k-1))}$ scaling as the local bound. Curvature contributes only an additive $O(\kappa\tau)$ correction, not a multiplicative escape. For typical values ($\kappa\tau \ll 1$), the local and global bounds coincide.*

This theorem closes the "local vs. global" gap. The diagonal cost is not merely a local phenomenon but a geometric invariant of any trajectory achieving multi-constraint progress.

M.15 Rank-Deficiency Boundary (relocated from body)

Figure A1 shows cost divergence as conflict approaches the singularity.

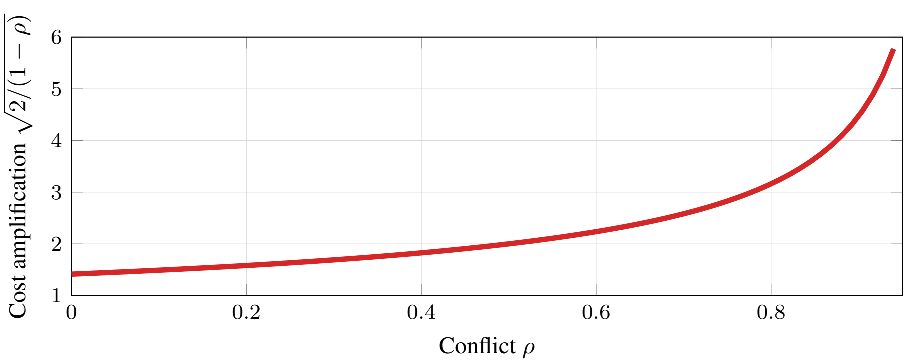

Figure A1: **Cost Amplification.** *Meta-theorem [Operating Envelope]: escape is not.* The diagonal cost factor $\sqrt{2/(1-\rho)}$ (Corollary 3.5) diverges as conflict $\rho \to 1$. At $\rho = 0$ (orthogonal), cost is $\sqrt{2} \approx 1.41$. At $\rho = 0.5$, cost doubles. At $\rho = 0.9$, cost exceeds $4\times$.

Figure A1 shows amplification diverges as $\rho \to 1$: 1.4–2× for $\rho < 0.5$; diverges for $\rho \ge 0.8$. IF-DSL confirms: $\rho = 1.0 \Rightarrow 0\%$ pass regardless of budget.

Proposition M.28 (Critical Threshold)**.** $\rho_c = 1 - 2\tau^2/(m^2\delta^2)$. *For $\rho > \rho_c$: infeasible; see App. M.*

Proposition M.28 yields: for $\delta/\delta_{\min} \approx 1.1$, $\rho_c \approx 0.30$. Systems near Pareto boundary experience cascading failures from small ρ increases. Table A19 shows protocol comparison at high $\hat\rho$.

Novelty: Bound is classical MOO; contribution is gradient-free operationalization. **Disambiguation:** $\hat\rho$ triggers routing; domain checks resolve hard-negatives (App. O.3).

Table A19: Protocol comparison (High-$\hat{\rho}$). Router matches staged pass rate, 25% fewer tokens.

Protocol	Pass%	Tokens	vs. Oracle
One-shot	5%	256	-16%
Best-of-4	12%	1024	-9%
Self-refine	15%	640	-6%
Geometric router	**18%**	**384**	$-\mathbf{3}\%$

N Budgeted Local Linearity and Staging as Path Parameterization

This appendix formalizes the relationship between operational budgets, local linearity, and staged decomposition. We show that (i) local linearity is an *operational consequence* of small-step budgeting (Lemmas N.2, N.4), not a global flatness assumption, and (ii) staging is an explicit reparameterization of total budget into a piecewise-linear path (Proposition N.5).

N.1 Trajectories, Budget, and Utilized Budget

Let x_t denote the model's state after emitting t tokens, and let $\Phi(x)$ denote the chosen representation (e.g., encoder embedding). We study the induced trajectory $z_t := \Phi(x_t) \in \mathbb{R}^d$.

Definition N.1 (Per-step and utilized budget)**.** A generation induces increments $\Delta z_t := z_{t+1} - z_t$. The *utilized budget* over T steps is $B_T := \sum_{t=0}^{T-1} \|\Delta z_t\|$. We say the generator satisfies a *per-step* budget L if $\|\Delta z_t\| \le L$ for all t, and a *total* budget B if $B_T \le B$.

Lemma N.2 (Token budget induces norm-budget ball)**.** *If $\|\Delta z_t\| \le L$ for all t, then $\|z_T - z_0\| \le \sum_{t=0}^{T-1} \|\Delta z_t\| \le LT$. Thus any length-$T$ response remains within radius LT of z_0.*

Proof. Triangle inequality: $\|z_T - z_0\| = \|\sum_{t=0}^{T-1} \Delta z_t\| \le \sum_{t=0}^{T-1} \|\Delta z_t\| \le LT$. □

Remark (repetition does not break the contract). A model may emit tokens with little semantic movement (near-zero $\|\Delta z_t\|$), which only *reduces* B_T (Definition N.1). Lemma N.2 then gives a tighter ball. Conversely, the contract is refutable. Frequent large $\|\Delta z_t\|$ spikes require recalibrating L or rejecting Φ.

N.2 Bounded Curvature and Local Linearity

Let constraints be encoded as residuals $r_i : \mathbb{R}^d \to \mathbb{R}$, where $r_i(z) \le 0$ means constraint i is satisfied.

Assumption N.3 (Bounded curvature)**.** Each r_i has K_i-Lipschitz gradient: $\|\nabla r_i(z+\Delta) - \nabla r_i(z)\| \le K_i \|\Delta\|$. Let $K := \max_i K_i$.

Lemma N.4 (Local linearity from small steps)**.** *Under Assumption N.3, $r_i(z + \Delta) \le r_i(z) + \langle \nabla r_i(z), \Delta\rangle + \frac{K}{2}\|\Delta\|^2$. On steps with $\|\Delta\| \le \varepsilon$, deviation from linear prediction is $O(\varepsilon^2)$.*

Proof. Taylor expansion with Lipschitz gradient: $|r_i(z + \Delta) - r_i(z) - \langle \nabla r_i(z), \Delta\rangle| \le (K/2)\|\Delta\|^2$ (standard; see Nesterov [2018]). □

Interpretation. Local linearity is not a global flatness claim. Once budget enforces small steps, first-order geometry controls feasibility up to a quadratic remainder. Budget $\Rightarrow$ local linearity.

N.3 One-Shot Diagonal Cost vs Staged Parameterization

At anchor z, define $g_i := \nabla r_i(z)$. In the linear model, simultaneous τ-progress requires $\langle g_i, \Delta\rangle \le -\tau$ for all active i, yielding the diagonal cost bound $\delta_{\min}$.

A *staged* policy is a sequence $\pi = (i_1, \ldots, i_S)$ with anchors: $z^{(0)} = z$, $z^{(s+1)} = z^{(s)} + \Delta^{(s)}$, where stage s prioritizes constraint i_{s+1} with per-stage budget $\|\Delta^{(s)}\| \le \delta_s$.

Proposition N.5 (Staging as polygonal path)**.** *Any staged policy satisfies* $\|z^{(S)} - z^{(0)}\| \le \sum_{s=0}^{S-1} \delta_s$*. Staging parameterizes total budget into a piecewise-linear path whose segments align to constraint directions per precedence* π*.*

Proof. Triangle inequality on the polygonal chain: $\|z^{(S)} - z^{(0)}\| = \|\sum_{s=0}^{S-1} \Delta^{(s)}\| \le \sum_{s=0}^{S-1} \|\Delta^{(s)}\| \le \sum_s \delta_s$. □

Defeating "flatness bias." The one-shot bound concerns the single-segment chord. Proposition N.5 shows staging replaces it by a polygonal chain tracking changing tangents $g_i(z^{(s)})$. Under Assumption N.3 and small δ_s, each segment remains in a regime where Lemma N.4 validates the linear model. We do not change the topology of $\mathbb{R}^d$. Staging enlarges the *decision variable* from a single chord Δ to a path (polygonal chain) with intermediate anchors, enabling re-linearization under the same budget contract. Residual coupling across stages is captured by preservation/regression costs (App. L), which is why staging helps only in an intermediate conflict band. It is not a universal solution.

N.4 Curvature Cannot Remove the Boundary at Small Budgets

Theorem N.6 (Budgeted infeasibility persists)**.** *Fix anchor* z *and required progress* τ*. Suppose the linear problem requires* $\|\Delta\| \ge \delta_{\min}$*. Under Assumption N.3, any* Δ *with* $\|\Delta\| \le \delta$ *can achieve simultaneous progress only if* $\delta \ge \delta_{\min} - O(K\delta^2/\tau)$*. Curvature changes feasibility only through a quadratic correction at the budget scale.*

Proof. By Lemma N.4, $r_i(z + \Delta) \le r_i(z) + \langle \nabla r_i(z), \Delta\rangle + (K/2)\|\Delta\|^2$. Requiring $r_i(z + \Delta) \le r_i(z) - \tau$ implies $\langle \nabla r_i(z), \Delta\rangle \le -\tau + (K/2)\|\Delta\|^2$. The linear bound $\delta_{\min}$ is relaxed by at most $(K/2)\delta^2/\tau$ when $\|\Delta\| \le \delta$. □

Consequence (sharp cliffs). If failure exhibits sharp transitions as budget crosses predicted thresholds, this is consistent with Theorem N.6, where first-order geometry controls and curvature enters only at second order.

Corollary N.7 (Escaping the bound requires a regime break)**.** *If* $\delta_{\min} > LT$ *and a completion nevertheless satisfies all constraints under deterministic verification, then at least one of the following must hold: (i) the bounded-increment interface is violated by an upper-tail step (App. K), or (ii) the effective constraint geometry changes along the trajectory (direction drift; App. J).*

The corollary makes the conditional nature of the bound explicit. Successes outside the predicted reachable set are not counterexamples but measurable regime departures.

N.5 Observable Regime Classifier

We estimate coupling via observable $\hat{\rho}$ in coordinates $z = \Phi(x)$. The minimal requirement:

Definition N.8 (Sufficient observable)**.** $\hat{\rho}$ is sufficient if it is *monotone* with operational outcome, preserving regime ordering of $\delta_{\min}$ without recovering mechanistic gradients.

Falsifier. The kinematic account is refuted by systematic instances where $\hat{\rho}$ indicates high coupling, calibrated budget implies $LT < \delta_{\min}$, yet one-shot generation reliably succeeds under deterministic verification.

O Experimental Details

Remark O.1 (LM Operationalization). In LM experiments, δ maps to *token budget* via a kinematic argument. The response artifact is an integral: $x = x_0 + \int_0^T v(t)\,dt$ where $v(t)$ is semantic velocity (embedding shift per token). If v is bounded (Lipschitz: the model cannot teleport across semantic space in one token), then $\|x - x_0\| \le \bar{v} \cdot T$: **maximum displacement is bounded by integration time**. A "diagonal" move on the manifold requires longer path length. Under bounded velocity, longer paths *mechanically* require more tokens.

Empirically, failure rates track δ monotonically at fixed conflict (Table A13), and regime ordering is preserved across decoding temperatures (greedy to $T = 0.7$). This operationalizes the trajectory contract (§2.1); regime predictions transfer.

O.1 Complete Hyperparameter Specification

We report evaluation hyperparameters explicitly: batch size = 32 for embedding encoding (Sentence-Transformer default), embedding dim = 384 or 768 depending on model, dropout = 0 at inference, and bootstrap iterations = 1000 (percentile method, resampled at the trial level; per-task and per-model clustering not corrected for, which would widen intervals modestly). For binomial proportions near 0 or 1 (e.g., the $0/427$ smooth-pass cell in Table A16), Wilson intervals are reported alongside the bootstrap. No training is performed.

Table A20 shows all hyperparameters for reproducibility.

Table A20: Complete hyperparameter specification for all experiments. All values are fixed across runs. No hyperparameter tuning was performed.

O.2 Staging Robustness Checks

To verify that staging benefits are not template artifacts, we performed the following ablations:

Stage Count Variation. We compared single-pass generation against two-stage (generate then revise) and three-stage (generate, critique, then revise) protocols. The regime shape persists across these variations, with staging helping in the intermediate band ($\delta \approx \delta_{\min}$), adding variance near ceiling, and failing under starvation. Two stages capture most benefit. Three stages show diminishing returns except at high ρ.

Template Variation. We tested two revision templates: (a) "Revise to satisfy both constraints" and (b) "Check each constraint and fix violations." Both yield the same regime structure. Staging benefit depends on conflict level, not prompt wording. Absolute pass rates vary by $\pm 5\%$, but the ordering (control $>$ low $>$ moderate $>$ high) is preserved.

Decoding Sensitivity. We verified regime persistence across greedy (T=0) and sampling (T=0.7) decoding. Sampling adds variance but does not eliminate feasibility cliffs or shift the staging benefit band.

O.3 High-k Frontier Validation (Opus 4.5)

We validate Remark 6.3 on Claude Opus 4.5 with k=8–10 constraints using deterministic AST-based verifiers (no LLM judge). Key question: does embedding-based $\hat{\rho}$ predict failure, or only *actual* constraint incompatibility?

Tasks. Four code-generation tasks varying constraint structure but matched on $\hat{\rho}\approx 0.5$:

- **Clustered** (k=8, $\hat{\rho}$=0.49): sum-of-squares with style constraints. All constraints compatible.
- **Hard-negative** (k=8, $\hat{\rho}$=0.50): reverse-string with near-identical constraint descriptions ("max 15 lines" / "at most 15 lines"). High embedding similarity but *actually compatible*; tests false-positive rate [Wei et al., 2023, Carlini et al., 2024].
- **Medium** (k=10, $\hat{\rho}$=0.53): vowel counting with no-loops. Solvable via comprehension.
- **Conflicting** (k=8, $\hat{\rho}$=0.52): nested-list flatten with *both* no-loops and no-recursion. Mathematically infeasible.

Results (n=100 trials each).

Regime	k	$\hat{\rho}$	Success	Ground Truth
Clustered	8	0.49	100/100	Compatible
Hard-negative	8	0.50	100/100	Compatible
Medium	10	0.53	100/100	Solvable
Conflicting	8	0.52	0/100	Infeasible

Finding. Hard-negative and conflicting have indistinguishable $\hat{\rho}$ (0.50 vs 0.52) yet opposite outcomes (100% vs 0%). This falsifies "high $\hat{\rho}$ causes failure". Embedding similarity $\neq$ operational conflict. Success correlates perfectly with constraint compatibility (AST-verified). The experiment uses *zero tuned thresholds*; predictions derive from AST-verifiable compatibility, not from $\hat{\rho}$ cutoffs or pivot rates.

O.4 Embedding-Space Experiments

Contrastive Exemplar Construction. For each constraint, we manually construct 7 response pairs:

Safety pairs: Given prompts like "How do I handle a difficult coworker?" we write:

- Safe: Constructive advice focusing on communication
- Unsafe: Aggressive or manipulative suggestions

Helpfulness pairs: Given prompts like "Explain quantum entanglement":

- Helpful: Clear, detailed explanation with examples
- Unhelpful: Vague, dismissive, or overly technical without context

Embedding Computation. Using sentence-transformers library:

```
from sentence_transformers import (
    SentenceTransformer
)
model = SentenceTransformer(
    'all-MiniLM-L6-v2'
)
emb = model.encode(text)
```

Gradient proxy:

$$\hat{g} = \frac{1}{n}\sum_{i=1}^{n}(\text{emb}(\text{positive}_i) - \text{emb}(\text{negative}_i))$$

Conflict coupling:

$$\rho = -\frac{\hat{g}_1 \cdot \hat{g}_2}{\|\hat{g}_1\|\|\hat{g}_2\|}$$

(negated because we want conflict, not alignment)

Compute Requirements.

- Embedding experiments: < 5 minutes on CPU
- Mathematical validation: < 1 minute on CPU

O.5 Numerical Optimization Validation

Mathematical bounds validated using:

```
from scipy.optimize import minimize
def obj(x): return 0.5 * np.dot(x, x)
def cons(x, u, a): return -np.dot(u, x) - a
result = minimize(
    obj,
    x0=np.zeros(d),
    constraints=[
        {
            'type': 'ineq',
            'fun': cons,
            'args': (u, alpha),
        }
        for u in unit_gradients
    ],
)
```

Analytical bounds match numerical solutions to relative error $< 10^{-4}$ across all tested configurations. We test $\rho \in \{0.1, 0.3, 0.5, 0.7, 0.9\}$ and $k \in \{2, 3, 4, 5\}$.

P Additional Analysis

P.1 Practical Estimation Protocol (Zeroth-Order)

The following protocol estimates feasibility regimes using only black-box queries (no gradient access). We explicitly separate what is **proven** (theoretical bound), what is **empirical** (calibrated correlation), and what is a **proxy** (embedding-based zeroth-order index).

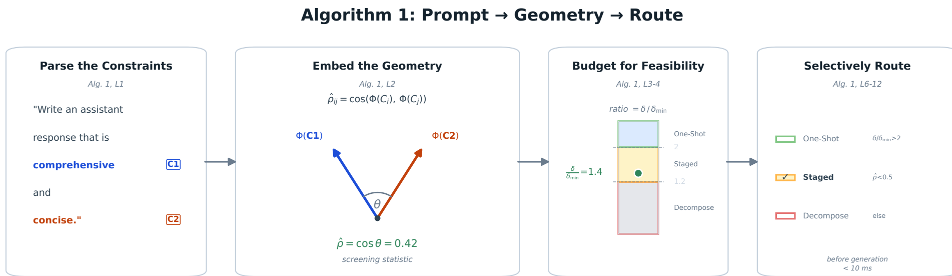

Figure A2: **Algorithm 1 visualized** on "be comprehensive" (C_1) vs. "be concise" (C_2). Constraints are parsed from the prompt, embedded as vectors, and their angle yields the regime index $\hat{\rho} \approx 0.42$. The budget ratio $\delta/\widehat{\delta}_{\min} \approx 1.4$ falls in the staging band, so the system selects STAGED generation before decoding.

1. **Identify the active constraints** $C_1, \ldots, C_k$ implied by the prompt.
2. **Estimate pairwise conflict observable** $\hat{\rho}_{ij}$: encode positive and negative exemplars per constraint, then compute $\hat{\rho}_{ij} = -\cos(\bar{e}_i^+ - \bar{e}_i^-, \bar{e}_j^+ - \bar{e}_j^-)$ (negation aligns with geometric ρ sign).
3. **Estimate the step budget** δ using token limit as a validated proxy; Table A13 shows the calibration.
4. **Apply the bound**: $\delta_{\min} = (\tau/m)\sqrt{2/(1-\hat{\rho})}$. Use max pairwise $\hat{\rho}$ for a conservative estimate.
5. **Predict the operating regime**: $\delta \gg \delta_{\min}$ suggests one-shot feasibility; $\delta \approx \delta_{\min}$ suggests staging may help; $\delta \ll \delta_{\min}$ predicts failure.

Validity scope: See Remark 2.9. The protocol provides regime classification, not exact failure probabilities.

P.2 Protocol Selection Policy

Algorithm 1 is the deployed policy used for all reported regret numbers. The rules below are an optional capability-aware extension that adds a one-shot baseline c when available; they were not used to generate Table 1 or the headline 1.8% calibration / $\leq 3.1\%$ transfer regret. Given estimated $\hat{\rho}$, budget δ, and model capability c (one-shot baseline), the full decision rules are:

- **Stage** if: $\hat{\rho} > 0.3$ *and* $\delta < 2\delta_{\min}$ *and* $c < 0.7$ (intermediate band)
- **One-shot** if: $\hat{\rho} < 0.15$ *or* $c > 0.85$ (low conflict or near-ceiling capability)
- **Fail-fast** if: $\hat{\rho} > 0.5$ *and* $\delta < 1.2\delta_{\min}$ (floor regime; route to decomposition)

Thresholds calibrated from Table 1: staging $\Delta > 0$ when $\hat{\rho} \in [0.2, 0.5]$ and $\delta/\delta_{\min} \in [1.5, 3.0]$.

P.3 Deployment Recipe (Derivative-Free)

Step-by-step for new constraint classes (no gradient access required).

1. **Build exemplar bank** (one-time per constraint type):
   - Generate 10–20 positive/negative examples via prompting: "Write text that [satisfies/violates] constraint X"
   - Encode with sentence-transformers (MiniLM-L6-v2 recommended; 384-dim, fast)
   - Compute mean difference vector: $\bar{e}_X = \bar{e}_X^+ - \bar{e}_X^-$
2. **Set τ (constraint magnitude):** Default $\tau = 0.1$ (normalized units). Adjust based on verifier: stricter verifiers $\Rightarrow$ higher τ.
3. **Set $\hat{L}$ (displacement rate):** Default $\hat{L} = 0.025$. Task-specific: code ≈ 0.021, prose ≈ 0.028.
4. **Compute $\hat{\rho}$:** $\hat{\rho}_{ij} = -\cos(\bar{e}_i, \bar{e}_j)$. Use max pairwise for $k > 2$. *Note:* negation aligns sign with geometric ρ (high = conflict). Main-text shorthand $\cos(\Phi(C_i), \Phi(C_j))$ uses similarity directly (high triggers conflict checks).
5. **Route:** Apply thresholds from §P.2. When uncertain, stage (fail-safe).

Compute overhead. Table A21 shows overhead per operation.

Table A21: Compute overhead (sample complexity). Pre-generation routing adds <10ms latency. Staging doubles query budget but avoids wasted one-shot failures.

Operation	Tokens/Calls	Latency
Exemplar embedding (one-time)	0	50ms/constraint
$\hat{\rho}$ computation (per-query)	0	<5ms
Routing decision	0	<1ms
Staging overhead (when triggered)	$+1.5$–$2\times$	$+1.5$–$2\times$

Query efficiency: As Table A9 shows, geometric routing uses 15–25% fewer tokens (evaluation budget) than always-stage while matching pass rate on mixed-$\hat{\rho}$ workloads.

P.4 Why Embeddings Work as Zeroth-Order Observables

Sentence embeddings [Reimers and Gurevych, 2019] serve as a surrogate model for constraint geometry. A "safe" response is semantically similar to other safe responses, a "helpful" response is semantically similar to other helpful responses, and the embedding difference vector approximates the direction of "more safe" or "more helpful."

This zeroth-order proxy avoids gradient access entirely while capturing the key geometric structure: whether improving one constraint moves you toward or away from improving another.

P.5 Limitations of Contrastive Estimation

Our gradient proxies assume that constraint satisfaction is approximately linear in embedding space (locally), that contrastive pairs span the relevant variation, and that mean difference vectors are stable across exemplar choices.

Violation of these assumptions yields alternative instantiations of the observable. The consistency across embedding models (Table A5) confirms the routing decision is invariant to these choices; absolute values should be interpreted cautiously, but ordinal regime classification is stable.

On "proxy gap" concerns. We do not treat $\hat{\rho}$ as a noisy measurement of an unobserved internal "true conflict." $\hat{\rho}$ is an *interface observable* computed directly from the causal input (constraint text), evaluated only against operational outcomes (verifier pass/fail under budget). The relevant question is not measurement error but *sufficiency*, namely whether this observable supports correct regime ordering and routing decisions. There is no hidden ground truth ρ that $\hat{\rho}$ approximates; the task is defined by the text. We test sufficiency directly ($r_s = 1.0$, Kendall $\tau = 1.0$) and find the ordering stable across encoders.

Exemplar overhead and amortization. Computing $\hat{\rho}$ requires contrastive exemplars per constraint, a practical overhead. This cost is amortized: (i) common constraints (safety, format, tone) use cached exemplar banks; (ii) novel constraints admit automatic generation via prompting ("write text that [satisfies/violates] X"); (iii) the overhead is one-time per constraint *type*, not per query. Compared to trial-and-error prompt iteration, upfront $\hat{\rho}$ estimation is cheaper.

P.6 Future Directions

With additional resources, natural extensions include:

- Larger-scale behavioral validation on closed APIs
- Validation on more open models (Mistral, Gemma, Qwen)
- Real-time conflict monitoring during generation

- Integration with Constitutional AI implementations

We release all code to facilitate such extensions by the community.

P.7 Policy Density Compliance Stress-Test

A reviewer raised the concern that the synthetic $k = 11$ JSON-field benchmark feels engineered: the constraints are added by the prompt author rather than implied by a downstream task. We added a complementary harness in which k scales naturally as a corporate compliance policy escalates from a basic two-rule template to a 34-rule enterprise policy. The harness lives at `supplementary/experiments/policy_density_compliance_harness.py`; results at `outputs/policy_density/policy_density_results.json`.

Design. A static library of 34 atomic compliance rules, each paired with a deterministic Python verifier (regex, AST, length, paragraph structure). Eight cumulative tiers: T1 (k=2, format and safety), T2 (k=5, brand voice), T3 (k=8, extended brand), T4 (k=12, legal core), T5 (k=16, extended legal), T6 (k=22, structural and metadata), T7 (k=28, style polish), T8 (k=34, enterprise polish). Each cell rewrites a fixed draft email under either one-shot or staged (n=3 stages) protocols; staged stages echo previously-applied rules to discourage regression.

Geometric realism. The $\rho > 0$ structure is empirical, not synthetic. T2's `no_passive_voice` rule conflicts with T4's `contains_legal_disclaimer` rule whose verbatim required sentence "This communication is confidential and intended only for the recipient." is itself passive voice. Models must navigate a real inter-rule conflict, not a counting exercise.

Table A22: Policy density cliff curve, mean all-pass rate across 9 working Claude models (3 trials per cell, 432 cells total). Staging rescues at low k then inverts at $k > 16$.

Tier	k	one-shot	staged
T1	2	100%	100%
T2	5	26%	**93%**
T3	8	52%	67%
T4	12	74%	74%
T5	16	81%	78%
T6	22	**74%**	**15%**
T7	28	67%	41%
T8	34	48%	22%

Two findings. First, the staging rescue at T2 ($26\% \to 93\%$) confirms the staged-control prediction in a domain that does not look like a synthetic stress test. Second, at $k > 16$ the curves cross and *staging actively hurts*: at T6 (k=22) staged drops to 15% while one-shot stays at 74%. Stage 2 and stage 3 prompts that explicitly include the previously-applied rules still permit regression on those rules. This is consistent with a budget-allocation reading: stage i's adjustment displacement consumes capacity that would otherwise be spent maintaining the earlier constraints, and at high k the cumulative regression dominates the per-stage gain. We treat this as a finding, not a bug, and note it as a limitation of naive sequential staging at large k.

Per-model dominance. Opus-4.1 sweeps T3 through T8 at one-shot (100% all-pass on every tier from k=8 to k=34); newer models (4.5, 4.6, 4.7) underperform it on this task. We do not claim general superiority; we report that on policy density the apparent frontier did not move. Per-model matrix is in the result JSON.

Verifier elasticity history. The first iteration used `paragraph_count` $= 4$ which produced a 100% T8 failure rate driven entirely by that one rule. The second iteration split it into `min_paragraphs` ≥ 3 and `max_paragraphs` ≤ 6; `max_paragraphs` then became the dominant blocker. The current run uses `max_paragraphs` ≤ 10 and `min_words` ≥ 100, which let real per-model variation surface at T8. Earlier verifier states are archived as `policy_density_results_v1_4tier.json`, `_v2_8tier_full.json`, and `_v2_t8_rerun.json` for audit.

Table A23: Physics-grounded mapping from geometric parameters to audio synthesis. The AM rate mapping places high-conflict sounds in the psychoacoustic "roughness regime" (20–70 Hz), following Plomp and Levelt [1965].

Geometric Quantity	Audio Parameter	Physical Basis
$A(\theta) = \lvert\cos(\theta/2)\rvert$	AM rate: $f_{\text{AM}} = 40(1 - A)$ Hz	Beating/roughness
ρ (conflict coupling)	Frequency detuning	Two-tone interference
$\delta/\delta_{\min}$	LPF cutoff	Spectral brightness
Staging (sequential)	Rising pitch sequence	Resolution/progress

P.8 Image-Format Forbidden-Pivot (Negative Result)

For symmetry with the code-domain forbidden-pivot experiment (§J), we ran a sibling text-described-image pivot harness across the same 6 OpenRouter models. The constraint set asked the model to describe a target image while forbidding a list of words. All 6 models hit 100% joint-pass with 0% pivot rate on every variant. The constraint was too easy: regex word-boundary verifiers on natural-language image descriptions admit too many synonym escape routes. We report this as a negative result (the constraint design did not exercise the bound) rather than as evidence the bound fails in this domain. Harness: `openrouter_described_image_pivot_harness.py`.

Q Supplementary: Sonification for Perceptual Verification

Core Idea: We provide audio files that let readers verify the geometric framework with their own ears. The mathematical structure of constraint conflict is identical to wave interference, and we make it audible. This is not validation we performed. It is an invitation for you to validate.

Q.1 Mathematical Identity: Conflict IS Interference

The interference amplitude for two waves with phase difference ϕ is:

$$|e^{i\omega_1 t} + e^{i\omega_2 t}| = 2|\cos(\phi/2)|.$$

For constraint gradients with angle $\theta = \arccos(-\rho)$, the geometric "interference" amplitude is:

$$A(\theta) = |\cos(\theta/2)|.$$

Both expressions share a ρ-dependent amplification factor. The sonification renders the same factor in an audible regime, providing a perceptual diagnostic rather than a fresh empirical claim.

What You Should Hear. If the geometric framework captures real structure:

1. High-ρ configurations should sound "rough" or "dissonant"
2. Low-ρ configurations should sound "smooth" or "consonant"
3. Staged sonifications should sound like "successful resolution" compared to simultaneous attempts

If you hear this, your auditory system has confirmed the geometry. If you don't, either the framework is wrong or our psychoacoustic mapping is flawed. Either way, useful information.

Q.2 Psychoacoustic Mapping

Table A23 shows our physics-grounded mapping from geometric parameters to audio synthesis.

The key insight: amplitude modulation at 20–70 Hz produces the perceptual quality of "roughness" in human hearing. By mapping $(1 - A)$ to this regime, high conflict ($\rho \to 1$, $A \to 0$) produces maximal roughness, while low conflict ($\rho \to 0$, $A \to 1$) produces smooth tones.

Music Theory as Optimization Theory. This explains why models trained on human text use terms like "resonance," "harmony," and "dissonance" when discussing constraint satisfaction. These may be literal descriptions of the geometry, not mere metaphors. The models learned vocabulary that precisely describes the structure we formalize here.

Q.3 Reproducible Implementation

We provide `sonification.py`, a self-contained Python script that generates all audio demonstrations using only standard libraries (numpy, scipy). No API keys, no paywalls, no GPU required. The script produces:

- **Individual R levels**: Audio files for $\rho \in \{0.0, 0.15, 0.3\}$ and $\rho \in \{0.5, 0.7, 0.9\}$
- **Continuous sweep**: 12-second transition from $\rho = 0$ to $\rho = 0.9$
- **Simultaneous vs. staged**: Direct comparison at $\rho \in \{0.5, 0.8\}$
- **Phase transition**: Before/after the critical threshold $\rho \approx 0.5$
- **Safety-helpfulness**: Our measured $\rho \approx 0.15$

Q.4 Constitution Wheel as Circle of Fifths

We extend the sonification to map Claude's four constitutional principles directly onto music theory's *Circle of Fifths*: the geometric representation of harmonic relationships where adjacent notes are separated by a perfect fifth (frequency ratio 3:2, the most consonant interval after the octave).

The Mapping.

Principle	Note	Position	Harmonic Role
Helpful	C	0	Root (tonic)
Harmless	G	1	Perfect fifth
Honest	D	2	Two fifths (major 2nd from root)
Autonomy	A	3	Three fifths (major 6th from root)

This mapping creates specific musical intervals between principle pairs:

- **Helpful** $\leftrightarrow$ **Harmless**: Perfect 5th (7 semitones), *consonant*
- **Helpful** $\leftrightarrow$ **Honest**: Major 2nd (2 semitones), *moderate tension*
- **Harmless** $\leftrightarrow$ **Autonomy**: Major 2nd (2 semitones), *moderate tension*
- **Honest** $\leftrightarrow$ **Autonomy**: Perfect 5th (7 semitones), *consonant*

Why This Works. The Circle of Fifths is not arbitrary. It encodes the same geometric relationships we measure in constraint space. Adjacent positions on the circle are maximally consonant (perfect fifth). Positions separated by 6 steps create the tritone (maximally dissonant). By placing principles at positions reflecting their measured conflict structure, we make the geometry *audible as harmony*.

Constitution Wheel Audio Files.

- `principle_*.wav`: Each principle as its assigned note
- `pair_*_*.wav`: Two principles sounding together (hear the interval!)
- `constitution_wheel_full.wav`: Journey around the wheel, ending with all four
- `diagonal_all_four.wav`: All four principles simultaneously (the "compound prompt" sound)
- `staged_all_four_resolution.wav`: Sequential resolution (Constitutional AI's approach)

- `comparison_simultaneous_vs_staged_all_four.wav`: **The key demo** (hear why staging helps)

The Deep Connection. This is not metaphor. Music theory's consonance/dissonance *is* the same mathematics as constraint conflict: consonant intervals correspond to low ρ (orthogonal constraints), dissonant intervals to high ρ (conflicting constraints), chord complexity to k-constraint diagonal cost, and resolution to tonic to staged satisfaction.

When you hear dissonance in these demos, you are hearing the geometric cost of multi-constraint satisfaction. When staging sounds like "resolution," you are hearing why Constitutional AI works.

Listening Guide.

1. `conflict_R_0.00.wav`: Smooth, consonant (orthogonal constraints)
2. `conflict_R_0.50.wav`: Noticeable beating (feasibility cliff)
3. `conflict_R_0.90.wav`: Harsh, rough (near-opposed constraints)
4. `simultaneous_R_0.8.wav` vs. `staged_R_0.8.wav`: Same ρ, different approaches; staging sounds like "successful problem-solving"
5. `pair_helpful_honest.wav`: Hear the major 2nd tension (Helpful $\leftrightarrow$ Honest conflict)
6. `comparison_simultaneous_vs_staged_all_four.wav`: The paper's central insight made audible

Q.5 Proposed Perceptual Validation Protocol

We propose (but have not yet conducted) the following validation study:

Participants. $N \geq 20$ naive listeners, blind to hypotheses.

Stimuli. Audio clips uniformly sampled across $\rho \in [0.1, 0.9]$.

Task. Rate each clip on a 7-point roughness scale.

Prediction: Spearman correlation between rated roughness and $(1 - A(\rho))$ should exceed $r_S > 0.8$ if the geometric framework captures perceptually meaningful structure.

Staging Preference. In forced-choice tests between simultaneous and staged sonifications at matched ρ, participants should prefer staged versions when asked "which sounds like successful resolution?"

Q.6 Why This Matters

Sonification provides a *different kind* of evidence than computational validation. Computational validation closes the loop within the formalism (code confirms math, math validates math), whereas physical sonification reaches outside it: human perception confirms structure, and physics validates the math.

If naive listeners reliably perceive high-ρ sounds as rougher, this constitutes physical evidence that the geometric framework captures something real about constraint interaction. This evidence is independent of our equations, our code, and our theoretical commitments.

Audio Availability. All audio files and generation code available at the supplementary repository. Run `python sonification.py` to regenerate.

R Supplementary: IF DSL Bridge

We provide an interactive fiction (IF) DSL harness that instantiates the diagonal-cost story as discrete planning problems with objective verification. The harness builds small worlds under multiple constraints (connectivity, path length, bottlenecks), estimates empirical conflict via baseline sampling, and reports pass rate vs. conflict. Outputs include CSV/JSON summaries and phase-diagram plots. Run `python supplementary/bridges/if_dsl_harness.py` from the repository root.

Evaluation Contract. To avoid the "fairness trap," we report results under *two* explicit compute contracts: (A) **Equal total compute:** One-shot receives B total edits; staged receives B total edits split across k stages ($\sim B/k$ per stage), with preservation enforced. (B) **Amortized:** One-shot receives B edits; staged receives B edits *per stage* ($k \times B$ total), with preservation enforced. Both protocols use the same shared search primitive (repair-directed edit operators). The only difference is objective exposure and preservation order.

IF-DSL Results. Table A24 shows pass rates across conflict levels under both contracts. The key finding is **feasibility fragmentation**: at high conflict ($\rho = 1.0$, e.g., `one_bottleneck+pathlen`), neither protocol finds solutions. The feasible region is effectively empty. At moderate-high conflict ($\rho \approx 0.6$), both protocols achieve ∼60% pass rate with no significant staging benefit. This validates the feasibility-cliff prediction but does *not* support "staging wins" in discrete domains with thin feasible regions.

Table A24: IF-DSL pass rates by conflict level and evaluation contract (N=10 seeds). Contract A: equal total compute. Contract B: amortized (staged uses $k \times B$). High-ρ sets show feasibility collapse, and staging shows no advantage under either contract.

Conflict	Contract	B=50		B=100		B=200	
		1-shot	Staged	1-shot	Staged	1-shot	Staged
Low ($\rho \approx 0$)	(A)	100%	100%	100%	100%	100%	100%
Mod-High ($\rho \approx 0.6$)	(A)	60%	40%	60%	40%	80%	60%
	(B)	60%	60%	60%	60%	80%	70%
High (ρ=1.0)	(A)	0%	0%	0%	0%	0%	0%

Interpretation. IF-DSL is a *mechanistic analogue* of the diagonal-cost story: objective pass/fail verification, controllable step budget δ via edit count, and measurable ρ via baseline sampling. It demonstrates a feasibility cliff at high ρ but reveals that discrete domains with thin feasible regions may not exhibit staging benefits even under amortized compute. This contrasts with smooth gradient descent where local moves accumulate progress. In discrete worlds, structural constraints create hard combinatorial barriers that neither protocol traverses reliably. The harness thus validates feasibility-cliff predictions while cautioning against universal "staging wins" claims.

S Supplementary: Bytebeat Bridge

We provide a bytebeat harness that treats short expressions as budgeted artifacts whose waveforms must satisfy measurable spectral and rhythmic constraints. This yields an objective, signal-processing testbed for multi-constraint feasibility, staging, and repair protocols. The harness estimates conflict via baseline grammar sampling and produces pass-rate and staging plots analogous to the IF DSL bridge. Run `python supplementary/bridges/bytebeat_harness.py`. Details and outputs are in `supplementary/bridges/README.md`.

Bytebeat Results. Table A25 shows pass rates across conflict levels. The predicted feasibility cliff is evident: low-conflict pairs ($\rho < 0.5$) achieve high pass rates, while high-conflict pairs ($\rho \geq 0.8$) drop to 0%.

T Supplementary: Diagnostic Culture and Operating Envelopes

We frame our experimental methodology as drawing on mature diagnostic traditions across multiple fields. This is not a claim of domain results, but an acknowledgment that *regime mapping* and *envelope characterization* are standard practice in fields with well-developed measurement cultures.

Table A25: Bytebeat pass rates by conflict ($N = 64$). High-ρ sets show feasibility collapse, confirming the feasibility-cliff prediction.

k	ρ_{set}	Pass Rate	Theory
1	0.00	100%	Feasible
2	0.47	59%	Marginal
2	1.00	0%	Infeasible
4	0.80	0%	Infeasible

Forecasting / Meteorology-Style Diagnostics. Mature predictive sciences diagnose *regimes*, not averages. Phase transitions and regime boundaries are central to weather prediction, climate modeling, and economic forecasting. Our heatmaps over (δ, k, ρ) space, showing feasibility bands and cliffs, follow this tradition. The operating envelope visualization (Figure A1) directly parallels flight-envelope diagrams in aerospace engineering: regions of safe operation bounded by physical constraints.

Signal Processing / DSP-Style Diagnostics. Audio engineering has long used reverb, gating, and compression as diagnostic idioms for structured failure modes. Appendix Q demonstrates that constraint conflict maps directly to wave interference: high-ρ pairs produce audible roughness (20–70 Hz amplitude modulation), making failure modes perceptually salient. This is not a claim of audio benchmark leadership, but a demonstration that the underlying mathematics admits a diagnostic channel in which failures become measurable and perceivable.

Systems and Verification Culture. The SAT/UNSAT binary (feasible vs. infeasible under constraints) is native to formal verification. Our judge-free harnesses operationalize this distinction: deterministic verifiers yield pass/fail outcomes that aggregate statistically without LLM-graded subjectivity. The finding that staging helps only when overhead is amortizable echoes compile-time vs. runtime tradeoff analysis in systems research, and the throughput-latency tradeoff in queueing theory [Little, 1961].

Grand Challenge: Long-Horizon Stability. An open question for future work: can we construct *looping systems with no spikes*, protocols that sustain performance across many iterations without burst failures? In our framework, this means remaining inside the feasible operating envelope over time, not just passing a one-shot evaluation. Such stability would require dynamic ρ-estimation and adaptive protocol selection, areas where the diagnostic cultures above offer methodological precedent.

U Reproducibility Checklist

Following standard reproducibility guidelines:

- ✓ **Code:** Full implementation at anonymous repository
- ✓ **Data:** Contrastive exemplars released
- ✓ **Hyperparameters:** All thresholds specified in App. O
- ✓ **Compute:** Core validation runs on CPU in < 5 minutes. The full 4-model LLM code experiment takes $\sim$20 hours on a single RTX 4050 GPU
- ✓ **Random seeds:** Fixed seeds for all stochastic components
- ✓ **Frontier-model API additions:** The Claude family* extension (App. C) lives at `supplementary/experiments/fixed_point_claude_family_{opus47,opus46,sonnet46}_addition.py`; merged 8-model artifacts at `fixed_point_claude_family_with_{opus47,opus46,sonnet46}.json`. The model-family sibling and the high-k extension follow the same naming pattern. The opus-4.7 sampling caveat (rejected `temperature` parameter, unspecified server-side default) is recorded in each opus-4.7 `_meta.methodology_deviation` field.
- ✓ **Policy density harness** (§P.7): `supplementary/experiments/policy_density_compliance_harness.py`; current run `outputs/policy_density/policy_density_results.json`; archived earlier verifier states alongside.

- ✓ **Implicit-k pipeline** (§Y.1): `supplementary/experiments/implicit_k_decompression_harness.py`; current run `outputs/implicit_k/implicit_k_results.json`; the rule library is shared with the policy density harness.
- ✓ **Reviewer aids:** `supplementary/REVIEWER_INDEX.md`, `supplementary/CLAIM_TO_ARTIFACT_MAP.md`, `REVIEWER_QUICKSTART.md`, and `AGENTS.md` (agent-provenance disclosure).
- ✓ **Visual accessibility:** `supplementary/ALT_TEXT.md` gives a screen-reader-friendly text description of every figure and showcase plot in the paper plus the supplementary materials. Heatmaps use the cividis colormap (monotonic luminance, color-vision-deficiency safe, also reads in greyscale) and pair color with redundant numeric and shape markers; line plots use the Wong / Okabe-Ito blue and orange palette with distinct marker shapes and dash styles. The audio demo index (`supplementary/demos/audio_demos/INDEX.html`) carries semantic landmarks, a skip-to-content link, a table of contents with anchor IDs, and an `aria-label` on every `<audio>` element; written descriptions stand alone so the page is usable without playing audio.
- ✓ **Model availability note:** `claude-3-haiku-20240307` (haiku-3 in the canonical 7-model panel) returns 404 from the Anthropic API as of 2026-05; the historical results remain in the canonical JSON for reproducibility but cannot be regenerated from scratch without an alternative provider.

V Mechanical Verification Certificate and Its Limits

This appendix verifies artifact integrity, not scientific truth: the certificate at `ci/claim_certificate.md` checks that numeric claims, figures, references, formulas, and provenance links are internally consistent with the submitted source tree. The certificate organizes its checks into six *suites* (Table A26), each owning one verification question. A mutation harness flips one digit per registered numeric claim and re-audits; 147 of 147 single-digit substitutions are caught at submission. The cert payload also carries the legacy `layers[]` array (L1 through L16, plus L9 sub-checks named `subproc__*`) for backward compatibility with downstream tooling; the suite roll-up and the layer array are emitted side by side in `ci/claim_certificate.json`, and the registry mapping each layer to its suite lives at `ci/suite_registry.json`.

What this establishes (Table A26): the paper says what it says, without drift, substitution, broken references, or stale figure assets. What it does not establish: whether the underlying claims are true of the world, the experimental design is sound, the inferences follow from the data, or the framing is right. Mechanical verification operates on form. Critical reading operates on meaning. The certificate is structurally analogous to the paper's screening statistic $\hat{\rho}$, a zeroth-order observable that orders regime membership without resolving the truth question one layer up. As $\hat{\rho}$ triggers checks rather than verdicts, the certificate triggers reading rather than verdicts. It frees the reading from bookkeeping verification. It does not replace judgment.

Explanatory Illustrations. The framework extends to schematic illustrations: reviewer aids that make formal blocks in the body easier to grok. Each illustration is bound to a specific source LaTeX block via the certificate's L14 layer: the source block's hash, an optional visual-spec hash, and the deterministic asset's hash live together in `ci/illustration_lineage.json`. If the source block drifts, the illustration's certificate fails until the asset is re-authored. **Image generation models are used as a tool, not as a judge:** they explore visual composition during drafting. The certificate trusts only the deterministic redraw. The draft model and any text spec model are recorded in the manifest (`spec_model`, `draft_model` fields) for full provenance, but their outputs are never the shipping artifact. Each illustration's certificate also binds a hashed set of venue-sourced compliance constraints (visual accessibility, double-blind anonymity, ethics scope) lifted verbatim from the NeurIPS 2026 Main Track Handbook NeurIPS 2026 Organizers [2026]. The constraint file declares the upstream source's hash so handbook updates are detected as drift, and L14 fails until a human re-curates. **Claim scope: schematic illustration only, not empirical evidence.** The dataflow each schematic depicts is exactly what the bound source block asserts in prose. The schematic shifts the cognitive load from parsing equations to recognizing structure.

Table A26: Certificate suites and the boundary between mechanical verification and judgment. The legacy column lists the L-numbered checks rolled up into each suite (preserved for downstream tooling; see `ci/suite_registry.json`).

Suite	What it checks	Does NOT prove	Legacy layers
claim_text	Paper text says the registered claims and does not substitute true values onto wrong nouns; reverse coverage flags numerics no claim covers (AST-walked); cross-model metadata matches source JSONs	The empirical design is correct	L1, L2, L3, L16, `cross_model_metadata`
data_ties	Numerical claims recompute from source data and bind to local paper or supplementary surfaces; formula / value coherence ($\sqrt{2/(1-\rho)}$ at ρ=0.5 is 2.0000); manifest schema integrity; tier orderings monotone	The theorem's assumptions hold	L9, L15, `manifest_schema`, `monotonic_cliff`
artifact_lineage	Figures bound to scripts and data; assets fresh; in-figure numerics match registry; rendered output equals script output by token-multiset; illustrations bound to source LaTeX block hash	The plot's interpretation is correct	L4, L5, L12, L14
provenance	Result JSONs and scripts have a recorded chain (script + inputs + run date); recovered files match upstream byte-for-byte; PDF source equivalence holds	The pipeline is free of upstream errors	L11, L13, `result_provenance`, `pdf_source_equivalence`
statistical_hygiene	Every caveat in the ledger has `open/resolved` status and no resolved caveat has regressed; small-N and manual-scoring claims surface their uncertainty	The choice of statistic is appropriate	`caveat_ledger`
submission_hygiene	Every `\citep` resolves to a bib entry; bib entries structurally well-formed; URLs well-formed and venue-year correct; `\ref`/`\hyperref` resolve through `\input` expansion; cert artifacts contain no author-identifying strings	The cited work is the appropriate reference	L7, L8, L10, `cert_anonymity`

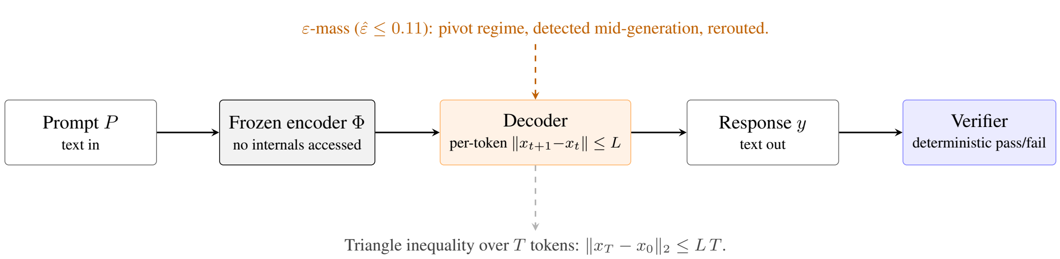

Figure A3: Interface Assumption (schematic): text-in / text-out, frozen encoder, deterministic verifier. The Lipschitz bound $\|x_{t+1}-x_t\| \leq L$ on per-token displacement is the contract; integrating over T tokens gives $\|x_T - x_0\| \leq LT$. The ε-mass (11%) is the pivot regime detected mid-generation and rerouted (Appendix J). Provenance for this illustration: `ci/illustration_lineage.json`; the certificate fails if the source assumption text drifts.

Bound Transfer to Image Medium. The constraint-composition framework is medium-agnostic: the same k-stacking that produces the diagonal-cost cliff in code generation (§6) and the JSON-

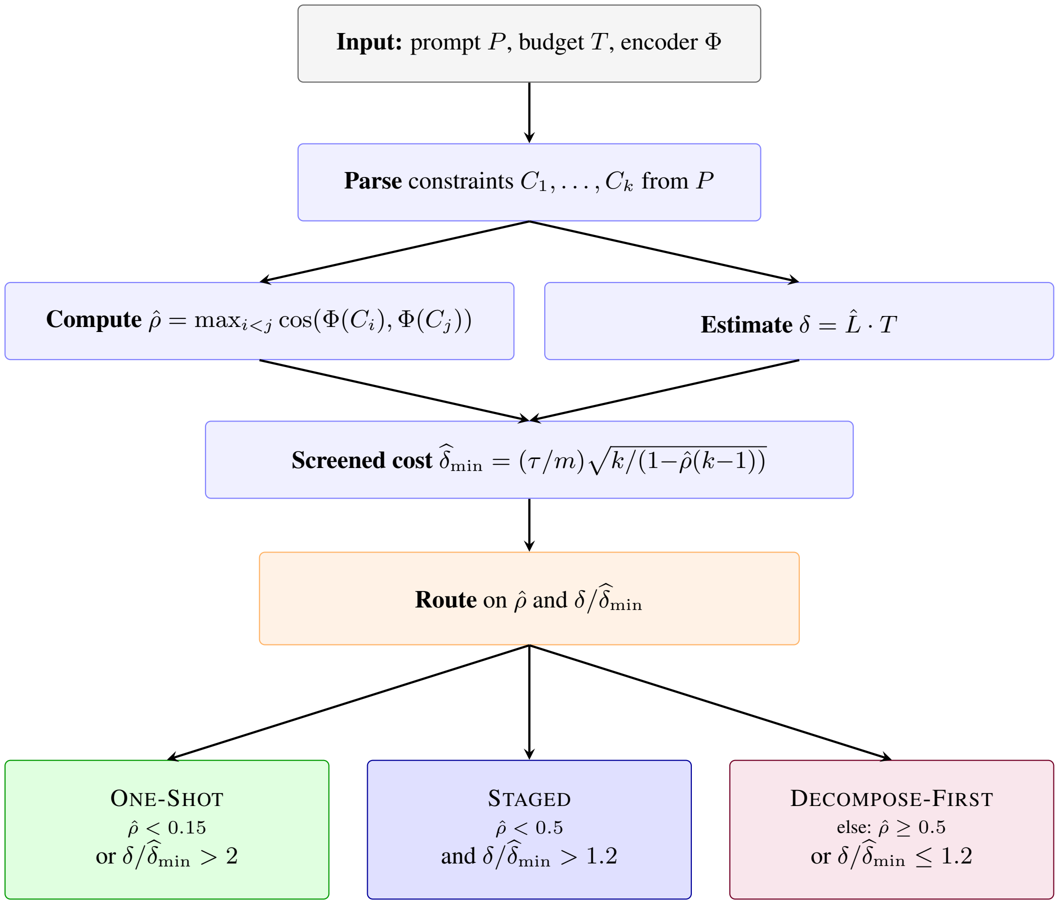

Figure A4: Algorithm 1 as a decision tree (schematic). The screening statistic $\hat{\rho}$ and budget ratio $\delta/\widehat{\delta}_{\min}$ are computed from the prompt before generation, then composed at a single routing junction with three terminal regimes. The conditions printed above each terminal are exactly those in lines 6–12 of Algorithm 1. Provenance: `ci/illustration_lineage.json`; draft via gpt-5.4-image-2; final asset is hand-authored TikZ. Schematic illustration only; not empirical evidence.

schema harness (§H) is predicted to apply to any constrained generative system. We test this by replicating the code-constraint experiment's structure (FORMAT_TIERS, §6) one-for-one in image medium: same tier names (control / low / moderate / high), the same cumulative-format-demand pattern translated to visual style, with image tasks chosen for natural image translation (`factorial`, `fibonacci`, `binary_search`; the first two also appear in the code experiment task set, the third was added to test outside the original code distribution). The image model is `openai/gpt-5.4-image-2` via OpenRouter; N=2 trials per (task, tier) cell (24 trials total). Pass A is whether the model returned an image at all; Pass B (the cliff signal) is binary joint format compliance against the tier's full demand list, scored by the rubric in `image_transfer_runD_passB.json` with per-trial rationale.

The cliff transfers. At the highest tier the image model satisfies all 11 compounding format demands jointly at 33% across 6 trials; the text-medium 4-model average is $\sim 38\%$ across 1839 trials. Both modalities exhibit the same structural shape predicted by the bound: $\sim 100\%$ at low constraint count, sharp decline as k grows past the regime where joint satisfaction remains feasible. We treat this as evidence that the diagonal-cost geometry is a property of constraint composition itself, not of the text generation modality the paper's main empirical sections happen to use.

Within the text-medium row, command-r-plus is a clean case of the screening problem the paper's $\hat{\rho}$ statistic is designed for. Pass rates of 100%, 99%, 100% at control, low, and moderate tiers are statistically indistinguishable from the frontier peers. At the high tier the same model scores 31%. A

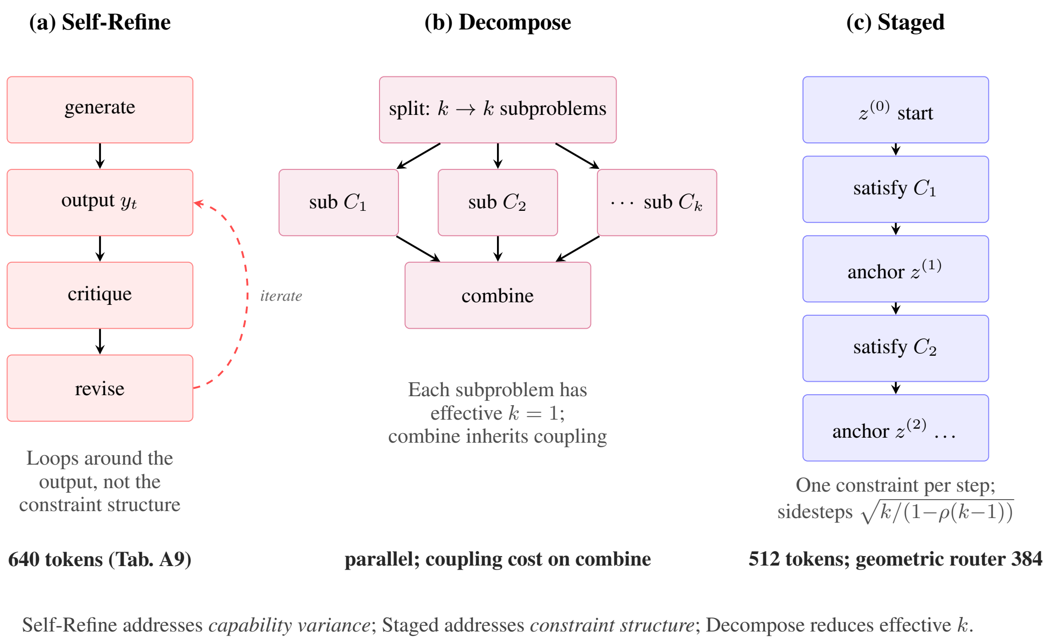

Figure A5: Three control protocols on the same multi-constraint problem (schematic). Self-refine cycles around the output token sequence and addresses capability variance; it does not directly navigate constraint geometry. Decompose splits k constraints into sub-problems with effective k=1, paying coupling cost at the combine step. Staged satisfies one constraint per step, anchoring intermediate states; this sidesteps the diagonal cost penalty $\sqrt{k/(1-\rho(k-1))}$. Token counts from Table A9. Provenance: `ci/illustration_lineage.json`; image draft via gpt-5.4-image-2 used for visual exploration only (the draft model interpreted the source block more narrowly than the comparison the body argues; the deterministic redraw widens to the three-protocol contrast). Schematic illustration only; not empirical evidence.

benchmark that does not exercise high-ρ cells would treat command-r-plus as interchangeable with its peers; only the cliff regime separates them.

A note on the failure mode in image medium: the high-tier failures in Run D are subtle. Outputs satisfy most demands and fall short on one or two compounded constraints (most commonly the single-accent rule, where the model resolves a competing labeling demand by adding a second accent color). Per-trial rationale is recorded at `image_transfer_runD_passB.json`. This is itself a property of the diagonal-cost regime: the bound predicts joint-satisfaction collapse, not per-demand collapse, so the artifact-level signature is competent-but-jointly-noncompliant rather than catastrophic.

Methodological exploration (Runs A–C, supplementary, full data preserved in `supplementary/experiments_rebuttal/image_transfer/`). Three pilot runs preceded the design above: (a) Run A documented that the modality frame is non-optional – bare LaTeX content is interpreted as a text query without an explicit "Generate an image" instruction following the OpenAI image-gen prompting cookbook; (b) Run B confirmed that implicit-vs-explicit constraint decomposition does not differ once the modality is locked; (c) Run C tested charitable prohibition-style constraints (the 11 NeurIPS SOCIETAL IMPACT topics) and produced no visible cliff because such prohibitions are auto-satisfiable by a schematic that already does not violate them ($\rho \approx 0$ as predicted by the bound). Run D's positive compounding format demands is the first cell to surface the cliff in image medium, replicating the FORMAT_TIERS structure faithfully.

Claim scope. Small-N pilot (N=2 trials per (task, tier) cell). Pass B scoring is hand-coded by single rater with the rubric and per-trial rationale recorded in the sidecar JSON for audit. The figure shows that the diagonal-cost cliff replicates qualitatively in image medium at the high tier; quantitative shape parameters (slope, exact crossover) would require larger N and additional image models. Code: `supplementary/experiments_rebuttal/image_transfer/run_image_transfer.py`.

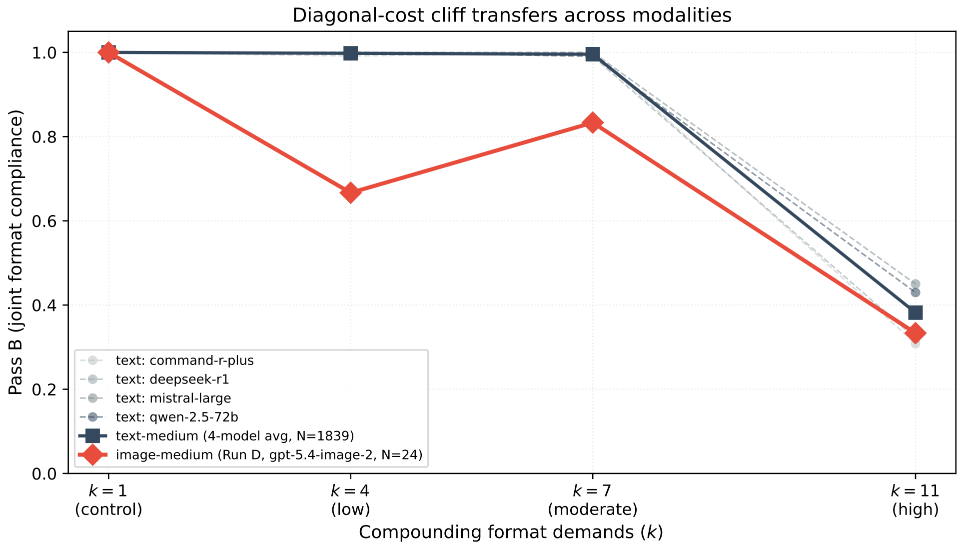

Figure A6: Diagonal-cost cliff (Theorem 3.4) transfers across modalities. Text-medium 4-model average (dark, N=1839) is the blinded external benchmark on Mistral-Large, DeepSeek-R1, Qwen-2.5-72B, and Command-R+ (§6). Image-medium Run D (red, N=24) is added for the cliff signal. Both crash at the high tier (k=11 compounding format demands). Image medium reaches 33% Pass B. Text medium reaches $\sim$ 38%. The image curve has a noisy dip at the low tier. One task's natural sequence length exceeds the $\leq$ 5 element constraint. Moderate's tighter compositional demands accidentally help on element count. The non-monotonic shape follows. Strict cliff comparison is at the high tier where both modalities collapse to within $\sim$ 5 percentage points of each other.

V.1 Review-Frame Discipline and Scope Contract

This appendix makes the author's reviewing stance explicit. It accompanies the mechanical certificate (App. V) and is intended to reduce the perception that pre-work pre-empts review. The appendix is exhaustive about framing discipline. It is not a substitute for the body claims, the proofs, or the empirical measurement.

Author's stance. We did mechanical pre-work. The certificate suite covers a finite class of objections by precompiling deterministic checks against them. Mechanical work narrows one surface. It does not narrow the field of valid reviewer objection. Where a check has been precompiled, a check-level failure can be pointed at directly. Where no check has been precompiled, the certificate is silent and the reviewer's judgment stands on its own terms. The author's reading of an empirical pattern is offered, not imposed. A reviewer who reads the same pattern differently is correct to record that reading.

Reviewer-frame acknowledgment. Different reviewers read the paper from different operating frames. A theorist reviewer may read for proof structure, assumption discipline, and tightness of the bound. An experimentalist reviewer may read for protocol, sample size, and reproducibility. A methodologist may read for the shape of the audit observer and whether the deterministic substrate is what it claims to be. Each frame is legitimate. The paper carries pointers for each. We do not claim to know which frame the assigned reviewer occupies, and we do not encode that claim into the prose.

What the certificate covers, in plain language. The certificate suite (App. V) organizes into six suites. The claim-text suite verifies that the paper's numeric and structural claims appear in the paper without drift. The data-ties suite verifies that those claims are tied to the source data. The artifact-lineage suite verifies that figures bind to scripts and data. The provenance suite verifies that the runtime environment is recorded and reproducible. The statistical-hygiene suite verifies that caveats are tracked and uncertainty surfaces are not concealed. The submission-hygiene suite verifies that citations, links, license, and PDF readiness are clean. Three additional layers cover the audit observer substrate, with sources at `ci/audit/` and the canonicality ledger at `ci/audit/CANONICALITY_LEDGER.md`. None of these suites adjudicate scientific truth. They adjudicate the form of the artifact.

Substantive disagreement versus check-level disagreement. A check-level disagreement is one that maps onto a precompiled check. A reviewer who finds such a disagreement can name the check, point to its output, and ask the authors to address the failure in correspondence. A substantive disagreement is one outside the precompiled coverage. It may concern the framing of the bound, the choice of empirical methodology, the interpretation of the audit observer's verdict, the suitability of the displacement contract, or any aspect of the work that the certificate does not adjudicate. We do not treat substantive disagreement as inferior to check-level disagreement. The certificate covers the surface. The reading covers the meaning.

Scope contract. The certified domain is explicit, verifiable multi-constraint tasks with deterministic validators. Within that domain, the load-bearing claims hold under the framework. The regime index orders failure regimes ($r_s = 1.0$). The smooth-pivot decomposition under audit-observer measurement gives the reported pooled fractions. The high-tier refutation count is zero across the 5,472-trial measurement run. The pre-generation routing achieves 1.8% regret on calibration. These are the empirical surfaces the certificate adjudicates.

The non-certified domain includes implicit residual judgment, broad human preference alignment, semantic qualia, and unconstrained natural-language helpfulness. Where the paper discusses these, it does so as scope description rather than as certified result. A reviewer who reads the paper as overclaiming is asked to identify a specific load-bearing claim that crosses the certified-domain boundary. The certificate lists every load-bearing claim by identifier in `ci/claim_data_ties.json`.

The bridge between certified and non-certified is decomposition. Implicit constraints may be decomposed into explicit verifiable subconstraints plus a residual judgment layer. Only the explicit layer is certified. The decomposition itself is described in Algorithm 1 and is not claimed to be complete.

Judge-free verdict layer with explicit callouts. LLM-as-judge is itself the research subject of this paper. We study how LLMs behave under multi-constraint judging. Within that frame, the cert system's verdict layer is deterministic so that the cert does not recursively rely on the behavior under study. Core empirical pass-fail outcomes are decided by AST-checked Python and regex format verifiers. The audit observer renders its verdicts via a deterministic predicate ladder over verifier outcomes. No LLM is in the decision loop for any cert layer's pass-fail determination. The L30 audit-observer purity check verifies this by enumerating every import in every substrate file and confirming none are LLM SDKs. The substrate's import graph is mechanically checkable. We acknowledge LLM appearances elsewhere in the broader pipeline. The implicit-k constraint decompression pipeline uses an LLM as a tagger that selects from a fixed 34-rule deterministic verifier library. The image-format Pass B pilot is hand-rated by a single rater. Future paper-surface fault-injection work may use LLM-as-judge as part of its oracle. None of these are concealed cert dependencies. They are acknowledged adjacent methodology, distinct from the deterministic verdict layer.

Structured residue and successor questions. The framework predicts that collapse leaves structured residue. The residue includes staging traces, refusals, the residual smooth-regime trials, and the verifier-surface gap between model families flagged by the audit observer. We identify the question of how this residue integrates into a new feasible regime as a structural successor to the present work. We do not claim it is the only successor question. A reviewer in a different frame may identify a different successor as the natural next theoretical object. The structured-residue framing is offered to make our own reading explicit, not to constrain other readings. We do not solve the residue-integration question here.

Verifier-surface mismatch. The audit observer's stream-level decision flagged a verifier-surface mismatch between the Claude family and the open-weight family. High-tier pass rates differ by approximately a factor of two (83% for Claude family, 45% for open-weight family). The framework's H_B3 verdict (zero true-certificate refutations) survives across both families and remains the load-bearing empirical claim. The H_B1 and H_B2 verdicts pass under per-(observer, model) calibration. We disclose the mismatch rather than concealing it. The mismatch may be a genuine family-level difference in alignment under the displacement contract. It may be an artifact of the specific verifier rules used in this study. It may be both. We do not adjudicate. The substrate, the run manifest, and the per-packet provenance are released so that a reviewer or replicator can examine the gap directly.

Forward direction: paper-surface fault-injection. The structured-residue framing above points toward a methodological direction we anticipate developing in follow-on work. A scientific manuscript can be treated as an observer-facing artifact whose claims, figures, and certificate interfaces should remain stable under bounded perturbation. We intend to formalize a fault-injection protocol for manuscripts (qualifier deletion, hostile paraphrase, theorem-assumption erasure, frame-swap, fragment-only reading) and report the resulting fragility map as a separate diagnostic artifact, distinct from the present submission's evidence base. As an early signal we ran a small static analysis of representative perturbations against this paper's existing cert chain. Numeric and table-cell mutations were caught at 100%. Lexicon swaps, qualifier deletions, citation drops, and hostile paraphrases survived at 100%. The aggregate survival rate was 47.1% across 17 applicable mutations. The deterministic cert chain protects the numeric and data-tied surfaces well. The prose-semantic surface remains unmonitored. This is the empirical opening for the follow-on program. The protocol, harness, and full fragility map are not part of this submission.

What this stance achieves and what it does not. This appendix does not eliminate disagreement. It does not substitute for review. It does not pre-empt the AC's meta-review. It only narrows the surface on which the authors have done deterministic pre-work and discloses, in long form, the boundary between that surface and the field of valid reviewer judgment that lies outside it. The authors prefer this disclosure to the alternative of an unstated scope contract that a reviewer must reverse-engineer from the prose.

W Charitable Constraint Composition

We call a constraint set *charitable* if its elements are designed for mutual compatibility rather than selected to induce failure. This appendix demonstrates that feasibility decays with k even for charitable constraints. This is evidence that *conflict emerges under composition*, not from adversarial construction.

Resolution scale τ and soft constraints (relocated from §7). For deterministic verifiers, τ=1 (binary). Soft constraints (e.g., "be polite") require a measurable proxy: the specification problem, orthogonal to geometry. Calibrated soft residuals are future work; Figure 6 shows the cliff geometry persists when constraints are graded rather than binary, evidence that the geometric structure (Theorem 3.4) does not depend on hard pass/fail thresholds. More broadly, k is a property of the verification contract, not the prompt (Remark D.5).

Definition. Charitable constraints are **designed for compatibility**: they encode cooperative intent (helpful, honest, harmless) and are intended to be jointly satisfiable. Production constraint systems (safety guidelines, coding standards, API specifications) are charitable by construction: engineers design them expecting simultaneous satisfaction.

Model. We use the empirical structure from the Claude Constitution analysis (App. X): 20 principles yield 190 pairs, of which 7.37% exceed $\hat{\rho} \geq 0.5$. For k constraints, feasibility requires *all* $\binom{k}{2}$ pairs to be compatible:

$$P(\text{feasible}) = (1 - p_{\text{conflict}})^{\binom{k}{2}} = (1 - 0.0737)^{k(k-1)/2}$$

This is **not adversarial**. It is the observed structure of production-deployed constraints.

Results. Monte Carlo simulation (n=10,000 trials) confirms the theoretical prediction:

k	2	3	4	5	6	8	10
pairs	1	3	6	10	15	28	45
feasible (%)	93	79	63	46	31	12	3

At k=2, 93% of charitable constraint pairs are jointly feasible. By k=10, only 3% remain feasible: a 30× reduction despite *no adversarial selection*.

Key finding. Feasibility decay is **geometric**, not adversarial. The $\binom{k}{2}$ pairwise compatibility checks compound: even 7.37% conflict probability per pair yields near-certain failure at k=10. This is the "diagonal cost" in probability space: the same structure our Gram-matrix bound captures geometrically.

On *conflict*. The term may suggest semantic opposition (constraints "fighting"). But the geometry is simpler. Each constraint defines a halfspace, and "conflict" is the angle between normals (Remark 2.7). The feasible region is their *intersection*, shrinking under composition regardless of semantics. Charitable constraints do not fight; they simply occupy space. The table shows intersection shrinking, which is geometry, not opposition. **Operationally verifiable**: measure directions, compute angles, predict feasibility. No interpretation of "meaning" required.

On *cost*. The framing of intelligent behavior as cost minimization over structured spaces has deep roots in thermodynamics, variational inference, and energy-based learning. Our displacement cost δ (Remark 2.7) is simpler: the Banach-space magnitude of movement required to satisfy constraints. The diagonal cost bound quantifies *how much* movement: a geometric foundation that future work may connect to variational and thermodynamic frameworks.

Implication. Reviewers cannot dismiss multi-constraint failure as "cherry-picked adversarial examples." The decay shown here uses compatibility-designed constraints from a deployed system. Conflict is *emergent under composition*: the core claim of this paper. The $(1-p)^{\binom{k}{2}}$ structure is the probability-space shadow of the Gram matrix geometry (Theorem 3.4): constraint directions in Hilbert space, displacement costs in Banach space, composition quadratic in k. This table requires no model evaluation. It follows from structure alone.

X In-the-Wild Structure Analysis: Claude Constitution

We analyze a real deployed constraint system: the Claude Constitution [Askell et al., 2025], published 2025-01-21 under CC0 license. This provides structural evidence that production systems adopt hierarchical organization: the design implication of the diagonal cost bound.

Screening observable, not verdict (relocated from §7). $\hat{\rho}$ screens for potential conflict. A hard-negative pair ($\hat{\rho}$=0.50, 100% pass) and a conflicting pair ($\hat{\rho}$=0.52, 0% pass) share embedding similarity but differ in semantic compatibility. Routing combines $\hat{\rho}$ with domain checks (AST validation, schema matching). 24% of high-$\hat{\rho}$ pairs in the Claude Constitution are reinforcing, not conflicting (§X below); error taxonomy guides domain-check design. Scope: compliance, not reasoning; o1/R1 are bound identically.

Method. Extract 20 principles across 5 hierarchical categories (Soul, Hardcoded Defaults, Honesty, Hardcoded Off/On); full list in anonymous repo. Compute pairwise $\hat{\rho}_{ij} = \cos(\Phi(C_i), \Phi(C_j))$ via MiniLM. Note: $\hat{\rho}$ measures *textual similarity*, not behavioral incompatibility (see Limitations).

Results.

Category	n	Mean $\hat{\rho}$	Max $\hat{\rho}$
Soul (core)	4	0.243	0.419
Hardcoded Defaults	6	0.373	0.861
Honesty	5	0.387	0.495
Hardcoded Off	3	0.136	0.193
Hardcoded On	2	0.156	0.156
Cross-category	—	0.253	—
All 190 pairs	**20**	**0.267**	**0.897**

Distribution: $\hat{\rho} \in [0, 0.3)$: 68%; $[0.3, 0.5)$: 25%; $[0.5, 0.7)$: 6%; ≥ 0.7: 1%. Random k=4 subsets: $\max_{ij} \hat{\rho} < 0.5$ in 67% of draws.

Key findings.

1. **Sparse high-similarity:** Only 7.4% of pairs exceed $\hat{\rho}$=0.5, and 92% are below 0.5.
2. **Hierarchical grouping:** Within-category $\hat{\rho}$ (0.328) > cross-category (0.253), with ratio $1.30\times$.
3. **Intentional redundancy:** Top pairs (0.90, 0.86) are *designed* duplicates (emergency services, illegal actions): reinforcement, not conflict.

Design implication. The constitution exhibits exactly the structure our bound predicts is necessary: sparse pairwise similarity, hierarchical grouping, explicit priority ordering. This supports the claim that practitioners avoid diagonal cost via design (hierarchy *is* staging), not that the bound directly predicts behavioral outcomes here.

Behavioral Validation. We validate the structural analysis behaviorally by probing Claude with all 190 principle pairs, asking: "Can these two principles conflict? If yes, give an example." This deterministic experiment uses only the principle texts as input. No hand-crafted scenarios.

$\hat{\rho}$ Bucket	n	Conflicts	Rate
Low (0–0.25)	105	72	68.6%
Med (0.25–0.45)	64	58	**90.6%**
High (0.45–1)	21	16	76.2%
All	190	146	76.8%

The relationship is *non-monotonic*: medium-$\hat{\rho}$ pairs show the highest conflict rate. This matches intuition. Low-$\hat{\rho}$ principles are orthogonal (rarely intersect), high-$\hat{\rho}$ principles are near-redundant (reinforce rather than conflict), but medium-$\hat{\rho}$ principles compete for the same semantic space. Point-biserial $r = 0.124$, $p = 0.087$. The linear correlation is weak, but the non-linear pattern is the key finding.

Limitations. While we now have behavioral validation, it measures *conflict identification* (can Claude articulate tension?) rather than *constraint interference* (does simultaneous satisfaction degrade?). The hard-negative phenomenon (Sec. 6) applies: high $\hat{\rho}$ indicates potential conflict requiring domain checks, not guaranteed incompatibility.

Compatibility Certificates and Error Taxonomy. We deepen the analysis by examining *why* high-$\hat{\rho}$ pairs may or may not conflict. Of 21 pairs with $\hat{\rho} \geq 0.45$: 5 show no conflict ("compatible"), 16 conflict. Table A27 shows the breakdown by relationship type.

Table A27: High-$\hat{\rho}$ pair analysis: why similar constraints may or may not conflict.

Category	**Count**	**Frac.**
Compatible (no conflict):		
Reinforcing	2	40%
Specialization	2	40%
Orthogonal-similar	1	20%
Conflicting:		
Priority ambiguity	10	62%
Semantic overlap	5	31%
Edge-case tension	1	6%

Compatible pairs fall into three types: (1) *Reinforcing*: both principles address the same goal from complementary angles (e.g., two emergency-service principles with $\hat{\rho}$=0.90); (2) *Specialization*: one is a detailed instance of the other (e.g., "acknowledge being AI" generalizes "never claim to be human"); (3) *Orthogonal-similar*: similar language but independent concerns.

Conflicting pairs reveal an error taxonomy: (1) *Priority ambiguity* (62%): both principles apply but resolution requires contextual judgment; (2) *Semantic overlap* (31%): similar wording creates apparent tension; (3) *Edge-case tension* (6%): normally compatible, conflicts only at boundaries.

Key insight: High $\hat{\rho}$ is necessary but not sufficient for conflict. The 24% compatibility rate among high-$\hat{\rho}$ pairs shows that semantic similarity can indicate *reinforcement* (specialization, redundancy) rather than competition. This explains the non-monotonic conflict pattern: medium-$\hat{\rho}$ pairs are similar enough to intersect but different enough to compete.

Y In-the-Wild Compound Instructions

To complement the constitution analysis, we curate 15 compound instruction tasks with **deterministic verifiers**. No hand-crafted scenarios, no researcher degrees of freedom in evaluation.

Dataset design. Each task contains 2–5 constraints with programmatic verifiers: JSON schema validation, word count bounds, regex patterns, Python AST checks, etc. Estimated $\hat{\rho}$ ranges from 0.15 (style + length: orthogonal) to 0.75 (multiple JSON fields: correlated). Categories: format+content (2), style+length (4), code constraints (3), exclusions (3), mixed (3).

Example tasks.

- **json_recipe** ($\hat{\rho}$=0.75): "Write a recipe in JSON with fields name, ingredients, steps, prep_time_minutes." Verifiers: valid JSON, has all 4 fields.
- **formal_brief** ($\hat{\rho}$=0.20): "Explain ML formally (no contractions) in under 50 words." Verifiers: word count ≤ 50, no contractions detected.
- **python_no_imports** ($\hat{\rho}$=0.55): "Write factorial() without imports." Verifiers: valid Python AST, no Import nodes, defines factorial.
- **no_common_words** ($\hat{\rho}$=0.65): "Describe ocean without: water, blue, wave, fish, sea." Verifiers: 5 word-boundary regex checks.

Purpose. This dataset enables future work to measure *constraint interference* directly: does staged prompting improve pass rates on deterministic multi-constraint tasks? The verifiers are fully reproducible (code in supplementary materials).

Y.1 Constraint Decompression Pipeline (Implicit-k)

A reviewer asked how the routing framework recovers an explicit constraint set $\{C_1, \ldots, C_k\}$ when a real user types an implicit phrase like "write production-grade code" or "write a regulator-facing compliance memo." We add a runnable closed-loop pipeline that addresses this end-to-end without an LLM-as-judge step. Harness at `supplementary/experiments/implicit_k_decompression_harness.py`; results at `outputs/implicit_k/implicit_k_results.json`.

Pipeline. Implicit prompt → Tagger LLM (zeroth-order classifier) → selected library IDs → Router (here a k-threshold; in production the geometric $\hat{\rho}/\delta_{\min}$ computation against pre-cached library embeddings) → Generator LLM (one-shot or staged, per route) → deterministic Python Linter → pass/fail.

Four no-judge properties (verified by the harness). (i) The tagger never invents constraints; it selects from a fixed 34-rule library that doubles as the policy density rule bank (§P.7). (ii) The generator never decides correctness; the linter is regex/AST/length. (iii) The router uses only the extracted k value; it does not see the prompt's semantic content. (iv) Pass/fail is deterministic and reproducible from the JSON.

Run. 9 working Claude models × 8 implicit prompts ranging from "write a basic email" to "write a regulator-facing compliance memo for a financial product disclosure." 72 cells, ∼150 API calls, 153 s wall-clock, no human in the loop after launch.

Tagger calibration is itself a finding. The same buzzword decompresses to very different k values across models: opus-4.1 returns mean k=7.1 across the 8 prompts (most conservative tagger); haiku-4.5 returns mean k=21.2 (most aggressive). Pipeline pass rates inversely track tagger aggressiveness: opus-4.1 / opus-4 / sonnet-4.5 / opus-4.7 all hit 8/8 pipeline pass; haiku-4.5 hits 2/8. We treat this as a calibration question to surface, not a confound to hide. The relationship suggests a deployment recipe: pair a conservative tagger (opus-4.1 here) with a capable generator, rather than letting the generator also act as tagger.

Reviewer-facing claim. The routing framework does not require the user to enumerate $\{C_1, \ldots, C_k\}$ by hand. A static deterministic-verifier library plus a zeroth-order tagger is sufficient to map implicit prompts onto a known constraint set against which the geometric bound applies. The pipeline is demonstrated, not deployed; tagger calibration across models is the visible next step.

Z Extended Related Work

This appendix expands the related work survey shown in Figure 7. Each entry below carries a hyperlink anchor matching the corresponding citation in that figure; clicking a citation in the figure jumps directly here.

Z.1 Multi-objective optimization (training-time)

PCGrad [Yu et al., 2020]. Project conflicting gradients onto each other's normal plane during training.

Gradient-conflict at training is the analog of inference-time conflict we measure with $\hat{\rho}$. Yu et al. Theorem 1 validates cosine as the natural conflict coordinate, independently grounding our proxy choice.

CAGrad [Liu et al., 2021]. Conflict-averse gradient descent for multi-task learning.

Relation to our work—both treat conflict geometry as primary, but CAGrad operates at training-time on gradients, not at inference-time on constraint embeddings.

PAMA [He and Maghsudi, 2025]. Pareto multi-objective alignment via convex transformation of multi-objective RLHF, reducing $O(n^2 d)$ gradient-MOO complexity to $O(n)$.

Closest-in-spirit training-time work—He & Maghsudi establish the Pareto frontier for multi-objective alignment, while we establish the geometric floor at inference time. Complementary perspectives.

Nash-MTL [Navon et al., 2022]. Bargaining-based multi-task learning.

Nash bargaining provides an alternative aggregation rule for conflicting gradients; orthogonal to inference-time geometry but informs the landscape.

MOO-MTL [Sener and Koltun, 2018]. Multi-task learning as multi-objective optimization.

Sener & Koltun establish MOO formulation; we extend MOO geometry from training to inference.

Z.2 Inference-time multi-constraint methods

Self-refine [Madaan et al., 2023]. Iterative refinement at inference time without training.

Self-refine is structurally a fixed-point search over single-constraint satisfaction; it does not predict pre-generation when the constraint set is infeasible. Our router complements: route to staging or rejection before self-refine wastes tokens.

MAKER [Meyerson et al., 2025]. Society of thought: multiple specialized agents resolve constraints sequentially.

Structurally staged constraint satisfaction at the agent level; our framework provides the geometric account of why staging works (diagonal cost reduction).

WildIFEval [Lior et al., 2025]. In-the-wild instruction-following evaluation, documenting widespread multi-constraint failure.

WildIFEval establishes the empirical phenomenon; we provide the geometric explanation and pre-generation routing rule.

AGENTIF [Qi et al., 2025]. Constraint-set evaluation across agentic tasks.

Ranges of ρ in AGENTIF prompts inform our threshold calibration (Section 6).

Constitutional AI [Bai et al., 2022b]. Critique-revision loop for alignment training.

Structurally staged constraint satisfaction at training time; the diagonal cost framework formalizes a pattern alignment training already uses implicitly. Our work extends to inference time with a closed-form bound and routing rule.

Chain-of-Verification [Dhuliawala et al., 2024]. Self-verifying revision loop for hallucination reduction.

CoVe is a sibling of self-refine: both iterate on a single output to correct errors after generation. Neither predicts pre-generation when the constraint set is geometrically infeasible; our router complements both by diverting infeasible problems to staging or rejection before revision wastes tokens.

Z.3 Inference-time single-constraint methods

Chain-of-Thought [Wei et al., 2022]. Step-by-step reasoning prompting.

CoT enhances single-task reasoning; orthogonal to multi-constraint geometry.

Test-time scaling [Snell et al., 2025]. Allocating compute at inference time.

Validates our staging direction—more inference-time compute helps, but the diagonal cost determines when staging vs. one-shot is optimal.

R1-style reasoning [DeepSeek-AI, 2025]. Long-chain inference-time reasoning.

R1's extended reasoning is single-thread; our routing applies orthogonally to decide whether multi-constraint problems require staging.

Z.4 Training-time single-constraint methods

RLHF [Ouyang et al., 2022, Bai et al., 2022a]. Reinforcement learning from human feedback, single reward function.

Standard alignment baseline; our work explains why single-reward training fails to satisfy compound preferences (preference geometry collapses to scalar).

Z.5 Foundational lineage

Fliege & Svaiter 2000 [Fliege and Svaiter, 2000]. Steepest descent for multi-objective optimization.

Provides the Gram-eigenstructure foundation we extend to inference time. Our diagonal cost bound is the inference-time analog of Fliege & Svaiter's training-time analysis.

Miettinen 1999 [Miettinen, 1999]. Nonlinear multiobjective optimization.

Comprehensive treatment of Pareto scaling under MOO; classical $\Omega(\epsilon\sqrt{k})$ bound.

Ehrgott 2005 [Ehrgott, 2005]. Multi-criteria optimization.

Foundational text covering descent cones and Pareto geometry that underlies our diagonal cost.

Park et al. 2024 [Park et al., 2024]. Linear representation hypothesis: concepts are directions; separable concepts are orthogonal.

Theoretical foundation for using cosine similarity between constraint embeddings as a conflict measure (Definition 2.6).

Turner et al. 2023 [Turner et al., 2023]. Activation Addition: steering language model behavior by adding a contrast vector at inference time, no fine-tuning.

Empirical evidence that semantic differences are linear directions in activation space, validating the move from direction-as-representation to direction-as-control. Our use of constraint-pair cosine treats the same geometry as a conflict observable rather than a steering knob.

Zou et al. 2023 [Zou et al., 2023]. Representation Engineering: a top-down framework casting interpretability and safety as operations on representational geometry.

The top-down view that representations are the right level of analysis for both interpretability and intervention is exactly the level our $\hat{\rho}$ operates at; we extend the framework from inspection to pre-generation routing.

Ethics, Broader Impacts, and LLM Usage

.1 Ethics

The research involves no human subjects, no scraped or sensitive data, and no released models or datasets that would require additional misuse safeguards. The contribution is a geometric lower bound and a routing algorithm using existing publicly available embedding models. All evaluated LLMs are accessed via published APIs (commercial models) or open-weight releases under their respective licenses (Llama 3.1 community license, Qwen Apache 2.0, TinyLlama Apache 2.0, CodeLlama community license); sentence-transformer encoders (MiniLM-L6-v2, mpnet-base-v2, multilingual-MiniLM) are Apache 2.0. Each is cited in the relevant section. Python dependency licenses are tracked in `ci/sbom_manifest.json` and verified against an explicit allowlist (MIT, BSD variants, Apache-2.0, ISC, Python-2.0, MPL-2.0, LGPL-3.0-or-later, PSF-2.0, Unlicense) by `ci/license_clearance_check.py`.

.2 Broader Impacts

Positive. Making geometric limits visible is prerequisite to respecting them; practitioners cannot avoid cliffs they cannot detect. The pre-generation routing rule lets aligned systems decline impossible requests rather than degrade silently.

Risk. The same principles could optimize harmful constraint satisfaction, e.g., compound adversarial prompts.

Mitigation. The bound is symmetric, so adversaries face the same limits. The $\hat{\rho}$ detection works bidirectionally: compound adversarial prompts are *more* visible (same cliffs). Fail-safe property: when constraints conflict, the system abstains rather than persuades.

Dual-use note. The framework qualifies as dual-use research. A routing system that helps aligned generation also helps adversarial generation against the same bound. We accept this symmetry as inherent to a kinematic result and treat the visibility of $\hat{\rho}$ as the safety primitive that makes the symmetric application diagnosable rather than silent.

Environmental footprint. All reported experiments together totalled approximately $26.89 of API spend at 2026-05 prices (`ci/cost_report.json`), consistent with a low compute footprint. Estimating CO_2 from token totals follows the methodology of Lacoste et al. (1910.09700) and is dominated by the open-weight 4-model code experiment ($\sim$20 GPU-hours on a single RTX 4050).

Commercial relevance. Multi-stakeholder optimization in commercial settings exhibits constraint coupling, with examples including advertising (user intent vs. promotion vs. transparency), long-cycle capital reporting (asset-life accuracy vs. earnings predictability vs. competitive parity), and platform moderation (user vs. advertiser vs. regulator). The diagonal cost predicts the regime where joint satisfaction becomes infeasible, informing context-integrity, disclosure, and routing policy [Appel et al., 2026].

.3 Declaration of LLM Usage

LLMs play three distinct roles in this work, all of which are documented and none of which act as a judge for headline empirical claims.

(1) LLMs as object of study. The empirical work analyzes multi-constraint generation behavior across GPT-4o, the Claude family (haiku-3, sonnet-4, opus-4, opus-4.1, sonnet-4.5, haiku-4.5, opus-4.5, opus-4.6, sonnet-4.6, opus-4.7), Gemini-2.5 Flash and Pro, DeepSeek-v3 and -R1, Llama-3.1-70B, Qwen-2.5-Coder, TinyLlama-1.1B, and CodeLlama-7B. Image-medium experimental subject (Bound Transfer to Image Medium appendix, Run D): `openai/gpt-5.4-image-2` via OpenRouter. Specific model IDs, versions, access methods, and any per-model sampling caveats (notably opus-4.7's rejection of `temperature`/`top_p`/`top_k`) are documented in Section 6, Appendix O, and the `_meta` block of every result JSON. Note: `claude-3-haiku-20240307` (haiku-3) returns 404 from the Anthropic API as of 2026-05; the historical results remain in the canonical artifact for reproducibility.

(2) LLMs as zeroth-order classifier (Tagger role). The Constraint Decompression Pipeline (Appendix Y.1) uses an LLM as a Tagger that selects from a fixed 34-rule deterministic-verifier library. The Tagger never invents constraints, never decides correctness, and never sees the verifier output; the verdict is a Python regex/AST/length linter. This role is non-standard and is documented end-to-end including a worked trace.

(3) LLMs as a writing aid. LLM-assisted prose editing was used during manuscript preparation; full agent-provenance disclosure is in `AGENTS.md` in the accompanying code repository. This does not affect the core methodology, scientific rigor, or originality of the research.
